INDEX.

ILLUSTRATIONS.

Abattoirs, Meat-Refrigerating Plants, Argentine, 829, 832
Absorption Brake. See *Dynamometer*
Abt Rack, Mountain Railways, 143
Abutment. See *Bridge*
Accident, British Naval Airship, 424
Accidents, Explosion, French Battleship "La Liberté," 432
Accident, S.S. "Olympic" and H.M.S. "Hawke," Collision, 429, 711
Accumulator. See under *Electric*
Acetylene-Oxygen Welds, Iron and Steel, Micro-photographs, &c., 844, 845
Admiralty Airship, Accident to, 424
— See under *Warships*
Aerial Propellers. See *Aeroplanes and Airships*
— Ropeways, Dam Construction, 132
— Ropeway, Ore-Washing Plant, 553, 554, 555
— See *Aeroplanes and Airships*
Aeronautical. See *Aeroplanes and Airships*
Aeroplanes and Airships:
Aerial Flight, Principles of, 312, 313
Aeroplanes, Angle of Attack, 312
— Definition of Sweep, 312
— Lifting Power at Different Speeds and Angles, 313
— Thrust Required at Different Angles, 313
— Wings, Effect of Aspect Ratio, 273
Airships, Army, "Beta" and "Gamma," 583
Airship, British Naval, Accident to, 424
— Models, Tests in Oblique Air Currents, 206
— Siemens-Schuckert, Action of Screws, 50
Army Aircraft Factory, Hydrogen Plant, 583, 584, 585, 586
Engines, Rotating Cylinder Type, Balancing, 360, 361
Göttingen Model-Testing Institute, Research Results, 206, 273, 548
Hydrogen Plant, Army Aircraft Factory, Farnborough, 583, 584, 585, 586
Lift and Drift, Airships in Side Winds, 206; Curved Plates, 273
Plates, Cambered, Effect of Aspect Ratio on Wind Pressure, 273
Wires and Ropes, Wind Resistance, 548
Agricultural Hall. See *Exhibition*
— Machinery Wheels, Pattern Plates for, 279
— Society, Royal, Norwich Show, 6, 7
— Tractors. See *Tractors*
Air-Compressors, Inertia Effects in Pipes, 168
— Robey's Steel-Plate Valves, 221
— Rotary (Escher Wyss and Co.), Plate XXVII., 86
— Steam-Driven (Murray, Workman, and Co.), 168
— Turbo (Brown, Boveri, and Co.), Plate VII., 45
— Turbo and Tests (Pokorny and Wittekind), 792, 793, 794
— Two-Stage (Robey), 220, 221
— Valves, Steel Finger Type, 168
Air Currents, Oblique, Effects on Airships, 206
— Fixation of Nitrogen, Electric Furnaces, 346
— Flow in Pipes, Inertia Effects, 168
— Gas Lighting Plant, "County," 177
— Measuring Nozzle, Turbo-Compressor, 793
— Pressure on Curved Plates, 273
— Pump. See *Pump*
— Resistance, Wires and Ropes, 548
— Velocity Measurement, Lea-Biram Anemometer, 541
— See also *Compressed Air* and *Pneumatic*
"Aki," Japanese Battleship, 16
Albula Works, Zurich; Hydro-Electric Power Plant, Plate XXXI, 153
Alloys, Aluminium, Effects of Annealing, 510
— Aluminium-Zinc, 439, 440
— Copper-Aluminium, Fatigue Tests, 557
— Copper, Effects of Annealing, 510
— Copper-Tin, Volume Changes during Cooling, 609, 610, 647
— Copper-Zinc, Corrosion of, 437, 473, 474
— Electrical Conductivity and Constitution, 545, 546
— Equilibrium Diagrams. See *Diagrams*
— Heating and Cooling Curves. See *Diagrams*
— Iron-Carbon. See also *Steel*
— Iron-Manganese, Effect of Carbon, 479
— Non-Ferrous, Use on L. and Y. Railway, 398, 399, 400, 401, 402, 433, 434, 435, 436
— See also *Micro-Photographs*
Alternating Stress Tests, Steel, Arnold's, 248, 557
— Stress, Bending and Torsion, Tests of Steel; Testing-Machine, 183, 184, 185, 306; Results, 247; Forms of Fracture, 248, 249; Micro-Photographs of Steel, 306
— Stress, Electromagnetic Testing-Machine, 696
— Stress, Rotating Beam Testing-Machine, and Results, 575, 576, 577, 578, 579, 580, 612, 613. See 557, 694, 695, 696, 697, 698, 731
Alternating Stress Tests, Arnold's, Copper-Aluminium Alloys and Steel, 557 See 248
— Stress Tests, Copper Trolley Wire, 580, 612
— Stress Tests, Different Cycles. 731
— Stress Tests, Elastic Hysteresis, 694, 696
— Stress Tests, Nickel-Steel, 580
— Stress Tests, Plotting, 612, 694, 695, 697, 698
— Stress Tests, Wire-Rope, 694
— Stress Tests, Wöhler's, 613, 694
— Stress Tests, Wrought Iron, Mild Steel, and Vanadium Steel, 557, 577, 578, 579, 580, 612, 613, 694, 695, 696, 697, 698, 731
Alternator. See *Generators* under *Electric*
Aluminium Alloys, Effects of Annealing, 510
— Copper Alloys, Fatigue Tests, 557
— Works, Neuhausen, Hydro-Electric Power Plant, Plate XXXI., 153
— Zinc Alloys, 439, 440
America, Shipping on Great Lakes, 64; Plates X., XI., and XII., 62
Ammeter, Frisby's Mechanical Magnetic, 503
Ammonal Explosives, Ltd.; Demolition of Bridlington Bridge, 491
Ammonia Compressors, Meat-Refrigerating Plants (Sulzer Brothers), 828, 832
Amsler's Dynamometers, 128, 129
Analysis, Gas, Carbon-Monoxide Recorder, 871
Anemometer, Lea-Biram, 541
Annealing, Effects on Steel, Aluminium and Copper Alloys, 510
Anschutz Gyro-Compass, 310
Anthracite Consumption, Suction-Gas Plants, 475, 476
Anti-Friction Metal, Bearings, Casting-Box, 435
Antimony-Copper Alloys, Conductivity, 546
Anti-Rolling Tanks, T.-S.S. "Laconia," 804, 805
Aqueduct, Catskill, New York, 119
Arch Bridge, Bridlington, Demolition, 491
— Bridge, Ferro-Concrete, Rome (Hennebique), 721, 722, 736; Plate LVIII., 721
— Bridge, Ferro-Concrete Staging, 721, 736
Archdale, J., and Co., Ltd.; Radial Drill, 630
Argentine (Central) Railway, Locomotive, 22
— Meat-Refrigerating Plants, 828, 829, 832
Argylls, Ltd.; Sleeve-Valve Engine, 591, 592
Armature. See *Electric*
Armoured Cruisers. See *Warships*
Army Aircraft Factory, Hydrogen Plant, 583, 584, 585, 586
— Airships "Beta" and "Gamma," 583
Arnold's Alternating Stress Tests; Copper-Aluminium Alloys and Steel, 248, 557
Artillery. See *Guns*
Ashokan Reservoir; New York Water pply, 118, 132
Atomiser, Oil-Fuel. See *Burner*
"Augustus B. Wolvin," Ore Steamer; Hold, Plate XII., 62
Australian Cruiser "Australia," Launch, 566, 571
Austrian Naval Dockyard, Pola, 120-Ton Floating Crane, 861, 862, 863, 866; Plate LXVI., 861
Autogenous Welds, Iron and Steel, Micro-Photographs, &c., 844, 845
Automatic Gun. See *Gun*
Automatic Machines. See *Machine-Tools*
Avery, W. and T., Ltd.; Percentage Weighing Machine, 652
Aviation. See *Aeroplanes and Airships*
Axle-Bearings; White-Metal Casting-Box, 435
— Boxes, Machine Moulding, 278, 725
Axle, Locomotive, Fractured, 749
— Motor-Car, Effect of Heat Treatment, 750

Baden; Brown, Boveri, and Co.'s Works, 45, 46; Plates VI., VII., VIII., IX., 45
Badische Maschinenfabrik und Eisengiesserei; Moulding-Machines, 186, 187, 619, 724, 728 853, 854
Baggage-Hoist, 2-Ton Electric, 458
Bahia Blanca; Meat-Refrigerating Plant, 828, 829
Bakers, Mixing and Kneading-Machine for, 563
Balancing Rotating-Cylinder Engines, 360, 361
Baldwin Locomotive Works; 2-6-6-2 Type Mallet Locomotive, Southern Pacific Railway, Plates LXIII., LXIV., 791
Ball-Bearings, Skefko Self-Aligning, 590
Ballistics, Smooth Bore and Rifled Guns, 93
Ballistite, Pressure and Composition of Gases, 94
Balloons. See *Aeroplanes and Airships*
Band Conveyor, Burnley Gas Works, Plate LI., 493
— Saws. See *Machine-Tools*
Banker and Co.; Motor-Boat, 196
Barbour Homopolar Dynamo, 318, 319
Barges, Bridge Erection by. See *Coteau Bridge*
— Canal. See *Canal*
Barry Transporter, 30-Cwt., 382, 383, 386
Battleships. See *Warships*
Beam Design, Use of Influence Lines, 689, 690
— Rotating, Testing-Machine, Alternating Stress, and Results, 575, 576, 577, 578, 579, 580, 612, 613. See 557, 694, 695, 696, 697, 698, 731
Beams, Ferro-Concrete Floor Slabs, Design, 857
Bear-Trap Dam, Trollhättan Power-Plant, 377
Bearings, Curtis Marine Turbine, 218
— Hinged, Bending Rolls, 486
— Railway Axle, White-Metal Casting-Box, 435
— Ring-Oiled, Pattern Plates for Moulding, 278
— See also *Ball* and *Roller*
Beck, R. and J., Ltd.; Grinding and Polishing Machine, Micro-Sections, 864
Bedplates, Engine, Erecting Vertically, 86
Belfast Municipal Technical Institute, Plates LIX., LX., LXI., LXII., 778, 779, 780
Belgian State Railways, 4-6-2 Type Passenger Locomotive, Plate LII., 525, 593, 594 595, 598; Plate LIV., 593
Belt Drive, Planing-Machine Tables and Feeds, Wicksteed's, 701, 704
Bending Rolls. See *Machine-Tools*
— and Torsion Tests, Alternating. See *Alternating Stress*
Bennis, Ed., and Co., Ltd.; Sprinkling Stokers, Mines de Dourges Works, 825
Bernese Oberland Railway, Locomotive, 145
Bern-Lötschberg-Simplon Railway. See *Lötschberg*
Bessemer Converter, "Stock" Oil-Fired, 53
Bevel Gears. See *Gears*
Beyer, Peacock, and Co., Ltd.; Locomotive, 22
Bickford's Toluene Blasting Fuze, 499
Biplane. See *Aeroplanes and Airships*
Biram-Lea Anemometer, 541
Birkeland-Eyde Electric Furnace, 541
Birmingham Small Arms Co., Ltd.; Motor-Car, 628
Bismuth Alloys, Electrical Conductivity, 545, 546
Bissell Trucks, Locomotive, 260, 315
Bisset's Reciprocating Feed, Saw-Benches, 796
Blade Angles, Steam-Turbines, Measuring, 551
— Tip Leakage, Steam Turbines, 551
Blades, Turbine, Flow of Steam, 245, 482, 730
— Turbine, Steam Friction, 729
Bladeless Steam-Turbine, Tesla's, 637
Blading, Curtis Marine Turbines, 216, 217 Plate XXXVI., 215
— Zoelly Turbine, 157, 160
Blast-Furnace Blowers, Turbo (Brown, Boveri, and Co.), Plates VI., VII., VIII., 45
— Blowing-Engine. See *Blowing-Engine*
— Gas-Engine. See *Engine, Gas*
Blasting, Cordeau Detonating Fuse, 491
Bleichert, A., and Co.; Wire Ropeway, Spain, 553, 554, 555
Bloom-Shearing Machine, Electric, 268
Blowers, Turbo (Brown, Boveri, and Co.), Plates VI., VII., VIII., 45
Blow-Pipe, Oxy-Acetylene, Iron and Steel Welding, Micro-Photographs, &c., 844, 845
— Producer-Gas, Pipe Welding, 486, 487, 488, 498
Boat, Motor. See *Motor-Boat*
— Patrol, for Turkey (Thornycroft), 462, 470
— See also *Launch*
Bogies, Four-Wheel, Locomotives, 260, 315, 598
Boiler Feed Pump. See *Pump*

ONE-PAGE AND TWO-PAGE ENGRAVINGS.

PLATE
I. Dunston Power Station, Newcastle Electric Supply Co., Ltd.: Elevations, Plan, and Switchboard Wiring Diagram (between pages 8 and 9)
II. Dunston Power Station, Newcastle Electric Supply Co., Ltd.: Interior of Engine-Room (facing page 8)
III. Dunston Power Station, Newcastle Electric Supply Co., Ltd.: Interior of Boiler-House, Series Transformers, Isolating-Switches, and Main Switches (between pages 8 and 9)
IV. Dunston Power Station, Newcastle Electric Supply Co., Ltd.: Induced-Draught Fan, A.E.G. Turbo-Alternator, Control-Room, and Switchboard (between pages 8 and 9)
V. Dunston Power Station, Newcastle Electric Supply Co., Ltd.: Switch-Gear (facing page 9)
VI. Brown, Boveri, and Co.'s Works, Baden: Machining Turbine Rotor, Turbo-Generator, and Turbo-Blowers (facing page 46)
VII. Brown, Boveri, and Co.'s Works, Baden: Turbo-Compressors and Blowers and Compressor Erecting-Shop (between pages 46 and 47)
VIII. Brown, Boveri, and Co.'s Works, Baden: Turbo-Blower under Test, Condenser Pumps under Test, and Electrical Winding-Shops (between pages 46 and 47)
IX. Brown, Boveri, and Co.'s Works, Baden: Winding Stator, Three-Phase Generator, Electrical Erecting-Shops, and Horizontal Three-Phase Generator (facing page 47)
X. Shipping on the Great Lakes: Duluth and Iron Range Co.'s Dock, Minnesota; Travelling Conveyors Unloading Iron Ore (facing page 64)
XI. Shipping on the Great Lakes: Hulett Ore-Unloading Machines (between pages 64 and 65)
XII. Shipping on the Great Lakes: Holds of Ore Steamers, Freight Steamer with Unloading Gear, Passenger Steamer "North West" (between pages 64 and 65)
XIII. Experimental Tank Tests, Submarine Models, Wave Profiles (facing page 65)
XIV. Sulzer Brothers' Works, Winterthur: General Plan, Foundry Cupolas, General View and New Shops for Heating Installations (facing page 82)
XV. Sulzer Brothers' Works, Winterthur: Views in Foundries (between pages 82 and 83)
XVI. Sulzer Brothers' Works, Winterthur: Heating and Ventilating Plant, Heavy Foundry (between pages 82 and 83)
XVII. Sulzer Brothers' Works, Winterthur: Heating and Ventilating Plant, Light Foundry (between pages 82 and 83)
XVIII. Sulzer Brothers' Works, Winterthur: Views in Foundries (between pages 82 and 83)
XIX. Sulzer Brothers' Works, Winterthur: Turbine Erecting-Shop, Boiler-Shop, and Delivery Bay (between pages 82 and 83)
PLATE
XX. Sulzer Brothers' Works, Winterthur: Diesel Engines in Erecting-Shop (between pages 82 and 83)
XXI. Sulzer Brothers' Works, Winterthur: Fitting and Erecting-Shop for Diesel Engines, Hydraulic Turbine-Rotor and Centrifugal Pump-Casing (facing page 83)
XXII. Escher Wyss and Co.'s Works, Zurich: Views in Foundry and Erecting-Shops (facing page 88)
XXIII. Escher Wyss and Co.'s Works, Zurich: Heavy-Machine Shop and Erecting-Bays for Condensers, Refrigerating Plants and Paper-Making Machinery (between pages 88 and 89)
XXIV. Escher Wyss and Co.'s Works, Zurich: Large Erecting-Shop, Vertical Turning and Boring-Machine, Machining Turbine Casing, and Erecting Hydraulic Turbine (between pages 88 and 89)
XXV. Escher Wyss and Co.'s Works, Zurich: Marine Steam-Turbines and Hydraulic Turbines under Erection (between pages 88 and 89)
XXVI. Escher Wyss and Co.'s Works, Zurich: Hydraulic Turbines under Erection (between pages 88 and 89)
XXVII. Escher Wyss and Co.'s Works, Zurich: Hydraulic Turbines and Turbo-Air-Compressor under Erection; Steam-Engine for Paddle Steamer; Boiler-Plate Bending-Shop (between pages 88 and 89)
XXVIII. Swiss Locomotive and Engineering Works, Winterthur: Erecting-Shops for Locomotives and Diesel Engines (between pages 88 and 89)
XXIX. Swiss Locomotive and Engineering Works, Winterthur: Locomotive Boiler-Shop, Turning and Fitting-Shops, and Gas-Engine Erecting-Shop (facing page 89)
XXX. Gas-Engines, Tandem, Four-Cycle, Double-Acting, and Alternators (Maschinenfabrik Thyssen and Co., A.-G.) (between pages 130 and 131)
XXXI. Oerlikon Engineering Works, Oerlikon: 10,000-H.-P. Turbo-Generators for Stockholm; Hydraulic Turbines and Generators, Albula Works, Schaffhausen and Neuhausen Aluminium Works (facing page 154)
XXXII. Oerlikon Engineering Works, Oerlikon: Iron Foundries, Fettling-Shop, and Steam-Turbine Department (between pages 154 and 155)
XXXIII. Oerlikon Engineering Works, Oerlikon: Electrical Erecting-Shops, Motor-Generators, and Power-House (between pages 154 and 155)
XXXIV. Oerlikon Engineering Works, Oerlikon: Small Motor, Crane Motor, and Switch-Gear Departments (facing page 155)
XXXV. Locomotive, 4-6-2 Type, Four-Cylinder Simple, Italian State Railways (Società Italiana Ernesto Breda) (between pages 192 and 193)
PLATE
XXXVI. Turbines, Steam, Curtis; United States Destroyers "Perkins" and "Sterrett:" Longitudinal Section and Elevations, Details of Rotor, Blading, and Diaphragms (Fore River Shipbuilding Co.) (between pages 216 and 217)
XXXVII. Locomotive, 4-6-2 Type Four-Cylinder Simple, Italian State Railways: General View, View in Cab, Longitudinal Elevation and Tender (Società Italiana Ernesto Breda) (between pages 258 and 259)
XXXVIII. Electric Traction in Switzerland; Bern-Lötschberg-Simplon Railway: Motor Carriage, Traction Motor, and 2000-H.-P. Locomotive (between pages 286 and 287)
XXXIX. Spanish Gunboat "Recalde:" Elevation, Deck Plans, and Sections through Machinery Rooms (Sociedad Espanola de Construccion Naval) (between pages 288 and 289)
XL. Locomotive, 4-6-2 Type Four-Cylinder Simple, Paris, Lyons, and Mediterranean Railway (between pages 314 and 315)
XLI. Steamer "Saguenay," Twin-Screw, Canadian; Elevation and Deck Plans (Fairfield Shipbuilding and Engineering Co., Ltd.) (between pages 350 and 351)
XLII. Trollhättan Hydro-Electric Power-Station; 12,500-H.-P. Francis Turbines (Nydqvist and Holm) (facing page 378)
XLIII. Trollhättan Hydro-Electric Power-Station; 12,500-H.-P. Francis Turbine, Machining and Erection (Nydqvist and Holm) (between pages 378 and 379)
XLIV. Trollhättan Hydro-Electric Power-Station: 12,500-H.-P. Francis Turbine, Machining and Erection (Nydqvist and Holm) (between pages 378 and 379)
XLV. Trollhättan Hydro-Electric Power-Station: Exterior Views of Power-Station and Instrument House, Erecting Electric Generator, and Interior of Machinery Hall (facing page 379)
XLVI. Skinningrove Iron Works, Electrical Rolling-Mill Plant: 1600-K.V.A Gas-Engine-Driven Alternator and Fly-Wheel Motor-Generator Set (Siemens Brothers Dynamo Works, Ltd.) (facing page 412)
XLVII. Skinningrove Iron Works, Electrical Rolling-Mill Plant: Fly-Wheel Motor-Generator Set and 12,000-H.-P. Reversing Motor (Siemens Brothers Dynamo Works, Ltd.) (between pages 412 and 413)
XLVIII. Skinningrove Iron Works, Electrical Rolling-Mill Plant: Fly-Wheel Motor-Generator and Control Platform (Siemens Brothers Dynamo Works, Ltd.) (between pages 412 and 413)
XLIX. Skinningrove Iron Works, Electrical Rolling-Mill Plant: General View of Cogging-Mill (facing page 413)
L. Coteau Railroad Bridge, River St. Lawrence: Plans and Elevations of Trusses, Strain Diagram, and Method of Erection (Dominion Bridge Co.) (between pages 448 and 449)
LI. Burnley Corporation Gas-Works Extension: Coal-Elevators and Conveyors, Coal-Crusher, and Vertical Retorts (between pages 494 and 495)
LII. Locomotive, 4-6-2 Type Four-Cylinder Simple, Belgian State Railways (Société John Cockerill) (between pages 592 and 593)
LIII. Winding Engine, 5500-H.-P. Two-Cylinder Corliss: Elevations and Plan (Sandycroft Foundry Co., Ltd.) (between pages 560 and 561)
LIV. Locomotive, 4-6-2 Type, Four-Cylinder Simple, Belgian State Railways: General View, Side Elevation, and Plan, Cross-Sections of Boiler and Fire-Box (Société John Cockerill) (between pages 592 and 593)
LV. Steamer "Newhaven," Turbine-Driven Cross-Channel: Longitudinal Section and Elevation, Deck Plans, and Cross-Sections (Société Anonyme des Forges et Chantiers de la Méditerranée) (between pages 642 and 643)
LVI. Submarine-Boats, Holland Type: Longitudinal and Cross-Sections (Electric Boat Co.) (between pages 656 and 657)
LVII. Engines, Oil, Marine, Junkers, Hamburg-America Liner (Actien-Gesellschaft "Weser") (between pages 698 and 699)
LVIII. Bridge, Ferro-Concrete Arch, Risorgimento, Rome: Longitudinal and Cross-Sections, and Details of Reinforcement (between pages 722 and 723)
LIX. Belfast Technical Institute: View of Exterior, Plan and Elevation of Engineering Laboratory (facing page 778)
LX. Belfast Technical Institute: Experimental Steam-Engine, Turbo-Alternator, De Laval Turbine and Pump, Refrigerating Machine (between pages 778 and 779)
LXI. Belfast Technical Institute: Hydraulic Turbines, Mechanics Laboratory, and Mechanical Engineering Workshop (between pages 778 and 779)
LXII. Belfast Technical Institute: Mechanical Engineering Laboratory (facing page 779)
LXIII. Locomotive, Mallet Compound, 2-6-6-2 Type, Southern Pacific Railway: Elevation, Cross-Sections of Boiler, and General View (Baldwin Locomotive Works) (between pages 790 and 791
LXIV. Locomotive, Mallet Compound, 2-6-6-2 Type, Southern Pacific Railway: Details of Boiler and Feed-Heater, Frame-Hinge, Truck-Centering Device, and General View (Baldwin Locomotive Works) (between pages 790 and 791)
LXV. Chinese Training Cruiser "Ying Swei:" General View, Elevation, and Deck Plans (Vickers, Ltd.) (between pages 826 and 827)
LXVI. Crane, Floating, 120-Ton Double Cantilever, Pola Dockyard, Austria: Elevations, Plan, and Sections of Ropes (Prager Maschinenbau A.-G.) (between pages 860 and 861)

Zeitung des Vereines deutscher Eisbahnverwaltungen, 167

LETTERS TO THE EDITOR.

Accident, "Olympic"-"Hawke" Collision. See "*Olympic*"
Adiabatic Expansion, Steam. Frank Foster, 798; A. G. Warren, 798
Aeronautical Research, Air-Pressure on Plates. A. W. Johns, 255
Aeronautical Research Society, East London College. R. H. Walters, 398
Air, Compressed, Power Transmission, Collieries. Jas. Dunlop, 876
Air-Pressure on Plates. A. W. Johns, 255
Air Supply, Steam Boilers, Effect of Moisture. T. B. Morley, 191
Alternating-Stress Tests, Comparisons of Cycles. C. H. Wingfield, 731
Alternating-Stress Tests, Effect of Annealing. IT.50, 840
Annealing and Fatigue Endurance, Metals. IT.50, 840
Armour for Ships. Chas. H. Jordan, 104
Armoured Concrete. See *Ferro-Concrete*
Army, Territorial, Engineer Officers. E. S. Sinnott, 398
Art and Science, Relative Values. See *Science and Art*

Belfast Technical Institute, Fuel-Economisers. D. Rushworth, for the Clay Cross Co., 798
Boiler Furnaces, Smokeless Combustion. Fraser and Chalmers, Ltd., 431
Boiler Insurance Companies and Power Plant Specifications. See *Power-Plant Specifications*
Boilers, Steam, Effect of Moisture in Air Supply. T. B. Morley, 191
Bonus for Hemp Machinery. John Holmes, 574, 875
Bridge, St. Paul's, London. O. B. I. T., 30, 79

Callendar's Researches, Properties of Steam. Frank Foster, 798; A. G. Warren, 798
Carbon Deposits, Cylinder Ports, Traction-Engine. James W. Harris and Son, 877
Case-Hardening, Dr. Giolitti's Process. F. J. Clinch-Jones, 711; Federigo Giolitti, 763
Civil Engineers, Institution of, Procedure at Meetings. Railway Member, 763
Clutch, "Vulkan" Magnetic, Planing-Machine Drives, Short-Stroke Work. W. Hargreaves, 840
Coal-Mines. See *Colliery*
College, East London, Aeronautical Research Society. R. H. Walters, 398
Collieries, Pneumatic Power Transmission. Jas. Dunlop, 876
Colliery Power-Stations, Gas-Engines for. Jas. Dunlop, 876
Collision, "Olympic"-"Hawke." See "*Olympic*"
Combustion, Smokeless, Boiler Furnaces. Fraser and Chalmers, Ltd., 431
Compressed-Air Power Transmission, Collieries. Jas. Dunlop, 876
Concrete. See *Ferro-Concrete*
Cranes, Large. J. W. Brown, for Cowans, Sheldon, and Co., Ltd., 30
Curtis Turbines, Test Results. F. Samuelson, for British Thomson-Houston Co., Ltd., 540; H. Zoelly, 631
Cylinder Ports, Traction-Engine, Carbon Deposits in. James W. Harris and Son, 877

Discussions at Engineering Institutions. C. Reginald Enock, 540

East London College, Aeronautical Research Society. R. H. Walters, 398
Economisers, Belfast Technical Institute. D. Rushworth, for the Clay Cross Co., 798
Education and Training, Engineers', Henry Spooner, 79; W. Morgan, 79; Stanley de Brath, 104; Experience, 164
Efficiency of Steam-Turbines. See *Turbines*
Eiffel's Experiments, Falling Plates. A. W. Johns, 255
Electric-Drive Planing-Machines, "Lancashire." W. Hargreaves, 840
Electrical Engineers, Institution of, New Articles of Association. R. Orsettich, 632
Endurance of Metals. See *Alternating Stress*
Engines, Gas, Colliery Power-Stations. Jas. Dunlop, 876
Engine Specifications. See *Power-Plant Specifications*
Engines, Steam, Carbon Deposits in Cylinder Ports. James W. Harris and Son, 877
Engineers' Education. See *Education*
Engineer Officers, Territorial Army. E. S. Sinnott, 398
Engineering Societies, Papers for Discussion. C. Reginald Enock, 540
Expansion, Adiabatic, Steam. Frank Foster, 793; A. G. Warren, 798

PATENT RECORD.

The Patent Index is classified under the following sub-titles:—Agricultural Appliances; Electrical Apparatus; Gas-Engines, Producers, Holders, &c.; Guns and Explosives; Hydraulic Apparatus; Lifting and Hauling Appliances; Machine and other Tools, Shafting, &c.; Milling and Separating Machinery; Mining, Metallurgy, and Metal-Working; Miscellaneous; Motor Road Vehicles; Printing and Allied Machinery; Pumps; Railways and Tramways; Ships and Nautical Appliances; Steam-Engines, Boilers, Evaporators, &c.; Textile Machinery; and Vehicles.

SUBJECT MATTER.

Electrical Apparatus:
82, 151, 212, 244, 339, 372, 403, 480, 515, 549, 582, 615, 653, 687, 752, 783, 815, 849, 880
Accumulator Boxes. G. E. B. Pritchett, 406
Ammeters. Siemens and Halske A.-G., 880
Arc-Lamps. J. O. Girdlestone and C. F. G. Thorkeln, 339
Arc-Lamps. Körting and Mathiesen A.-G., 372, 752
Arc-Lamps. Siemens Schuckertwerke, 549
Arc-Lamps. Siemens Schuckertwerke, 849
Arc-Lamp Suspension. J. Stevenson and O. R. Williams, 406
Brushes. General Electric Co., 815
Condensers, Electric. Siemens-Schuckertwerke, 151
Current Transformer. Siemens and Halske A.-G., 849
Cut-Outs, Electric. M. J. Railing and C. C. Garrard, 339
Cut-Outs. A. C. Reyrolle and A. Reyrolle and Co., Ltd., 480
Dynamo-Electric Machines. Siemens Brothers Dynamo Works, Ltd., and C. A. B. D. Koettgen, 406
Dynamos. H. Leitner, 783
Fuses. Siemens Schuckertwerke, G.m.b.H., 406
Generators, Alternating-Current. A. G. Brown, Boveri, 372
Hot-Wire Measuring Instruments. Hartmann and Braun A.-G., 687
Lamps, Electric. G. Ludecke and the Imperial Lamp Works (Brimsdown), Ltd., 82
Mercury Vapour Apparatus. Hartmann and Braun A.-G., 339
Meters, Electricity. Chamberlain and Hookham, Ltd., and S. James, 372
Meters, Electricity. G. Hookham, 212
Meters, Electricity. W. S. Sprague and Chamberlain and Hookham, Ltd., 815
Meters, Prepayment, Electricity. H. Aron Elektrizitäts-Zahlerfabrik, G.m.b.H., 82
Motors, Electric. J. C. Crawshaw and the Phœnix Dynamo Manufacturing Co., Ltd., 582
Motors, Induction. British Thomson-Houston Co., Ltd, and J. Martin, 615
Motor-Starters. M. B. Field and Ferranti, Ltd., 339
Polyphase Series Motors. Siemens Schuckertwerke G.m.b.H., 515
Potential Regulators for Generators. Allgemeine Elektricitäts Gesellschaft, 244
Rheostats, Motor-Starting. W. F. Perry, 653
Switches. A. F. Berry, 637
Switches, Electrical. Electric and Ordnance Accessories Co., Ltd., and N. Collins, 372
Switches, Electrical. A. W. Penrose, 151
Switches, Electric. M. J. Railing and C. C. Garrard, 687
Switches. Spagnoletti, Ltd., and V. E. Joyce, 849
Telephone Receivers. M. S. Conner, 244
Terminals, Electrical. A. P., G. C., and P. A. Lundberg, 849
Voltage and Current Regulation. W. J. Poole, 244
Voltaic Cells. S. Benko, 582
Wireless Telegraphy. J. A. Fleming, 783
Wireless Telegraphy. Marconi's Wireless Telegraph Co., Ltd., and H. J. Round, 615

Gas Engines, Producers, Holders, &c.:
82, 151, 212, 244, 406, 443, 480, 549, 582, 653, 687, 752, 783, 815, 849, 880
Calorimeters, Gas. A. Macklow-Smith, 406
Carburettors. P. A. Poppe, 849,
Engines. E. Crowe and E. Crowe, 783
Forced-Lubrication Apparatus. W. F. Rainforth and D. Napier and Son, Ltd., 752
Gas-Producers. T. W. S. Hutchins, 815
Gas-Producers. A. Wilson, 687
Ignition Arrangements. Firm Robert Bosch, 212
Internal-Combustion Engines. C. Y. Knight, 582
Internal-Combustion Engines. The Birmingham Small Arms Co., Ltd., and R. Nicholls, 406
Internal-Combustion Engines. E. Ashworth, 653
Internal-Combustion Engines. Firm Robert Bosch, 212
Internal-Combustion Engines. J. Hay, 82
Internal-Combustion Engines. F. Lamplough, 582
Internal-Combustion Engines. F. W. Lanchester, 653
Internal-Combustion Engines. J. C. Merryweather, 549
Internal-Combustion Engines. C. B. Redrup, 752
Internal-Combustion Engines. L. Renault, 880
Internal-Combustion Engines. B. S. and F. S. Roberts, 687

Gas Engines, &c.—*continued.*
Internal-Combustion Engines. F. H. Royce and Rolls-Royce, Ltd., 849
Internal-Combustion Engines. W. J. Still, 443
Internal-Combustion Engines. C. L. Sumpter and H. K. Foster, 549
Oil-Engines. E. W. Petter, 783
Pistons. C. Y. Knight, 480
Pistons. W. J. Lloyd, 241
Pistons. F. H. Tanner, 752
Producers, Gas. D. Clerk, H. N. Bickerton and W. Bradley, 151
Producers, Gas. W. Jones, 403
Producers, Suction-Gas. W. H. Moore and Ambrose Shardlow and Co., Ltd., 783
Valve-Gear. The Wolseley Tool and Motor-Car Co., Ltd., A. A. Remington, and A. J. Rowledge, 549

Guns and Explosives:
82, 151, 212, 244, 339, 443, 480, 549, 582, 815, 849
Automatic Guns. Sir A. T. Dawson and G. T. Buckham (two patents), 849
Breech-Block Gear. Sir A. T. Dawson and G. T. Buckham, 582
Fuses. Fried. Krupp A.-G., 151
Gun-Mountings. Sir A. T. Dawson and G. T. Buckham, 549
Ordnance. Fried. Krupp A.-G., 815
Ordnance-Training Gear. R. H. S. Bacon and F. Duncan, 82
Percussion Fuses. R. H. S. Bacon and R. Redpath, 480
Percussion Fuses. E. Schneider, 151
Projectiles. Sir A. T. Dawson and L. Silverman, 815
Projectiles. Fried. Krupp A.-G., 443
Projectiles. H. Stanbridge, 339, 244
Recoil and Running Out Gear. Sir A. T. Dawson and G. T. Buckham, 212
Sighting Apparatus. Sir A. T. Dawson and G. T. Buckham, 582
Small Arms. P. Mauser, 549
Torpedoes, Automobile. A. E. Jones, 151
Torpedoes, Automobile. Whitehead and Co. A.-G., 443

Hydraulic Machinery:
244, 687
Hydraulic Apparatus. H. S. Hele-Shaw and F. L. Martineau, 687
Suction Apparatus. W. J. Frame, 241

Lifting and Hauling Appliances:
82, 113, 151, 339, 443, 515, 615, 880
Capstans. J. A. Liddle, 113
Derrick-Cranes. Sir William Arrol and Co., Ltd., and E. Jullien, 515
Driving Systems, Electrically-Operated. Crompton and Co., Ltd., J. C. Macfarlane, H. Burge, and A. Williams, 82
Haulage Clip, J. W. Smallman, 443
Hoists. Adamson, Ramsbottom, and Co., Ltd., and H. Ramsbottom, 615
Hoists. G. C. C. Henderson, 151
Lifting-Jacks. W. Adair, 880
Pulley-Block. Tangyes, Ltd., and E. Johnson, 339

Machine and other Tools, Shafting, &c.:
113, 152, 340, 615, 783, 816, 850
Drills, Electric. A. Stewart and the Westminster Tool and Electric Company, Ltd., 152
Drills, Twist. B. O'Reilly, 152
Driving-Chains. H. Renold, 783
Friction-Clutch. G. H. Broadbent, 615
Friction-Clutches. Daimler Motoren Gesellschaft, 113
Gearing. A. C. and J. King and F. Hamer, 816
Gearing, Toothed. F. Humphris, 850
Multiple Disc-Clutches. Croft and Perkins, Ltd., and H. Lindsay, 816
Turning-Mills, A. E. Bennett and H. Thompson, 340

Mining, Metallurgy, and Metal Working:
212, 340, 443, 515, 550, 653, 688, 752, 880
Boring-Machines. A. Drummond, 443
Coal-Cutting Machines. Mavor and Coulson, Ltd., and A. W. Davies, 653
Coal-Washing Machinery. O. Sheppard, 688
Colliery Corves. D. J. Davies and L. Roderick, 752
Conveyors. J. Allardice, 550
Foundry Ladles. W. J. Caulfield, 212
Lamps, Miners'. T. Jones and T. R. Davies, 880
Pyrometer, Thermo-Electric. F. Stroude and E. Josephs, 515
Safety-Lamps, Miners'. E. A. Hailwood, 653
Steam-Crane Excavators. D. Whitaker, 340

Miscellaneous:
212, 654, 688, 784, 850
Advertising Lantern. A. T. C. Rosander, 784
Fans, Centrifugal. J. Keith and C. Tuson, 850

Miscellaneous—*continued.*
Flying-Machines. H. D. de M. Carey, 654
Glazing. J. A. King, 654
Gyrostats. R. H. Barbour and E. K. Scott, 654
Liquids, Atomising. Heenan and Froude, Ltd., and W. Wheal, 212
Testing of Materials. G. Kapp, 683

Motor Road Vehicles:
82, 113, 212, 340, 515, 615, 688, 815, 850
Automobile Vehicles. The Daimler Motor Co. (1904), Ltd., and F. M. Charles, 850
Change-Speed Gears. Daimler Motoren-Gesellschaft, 515
Clutch Mechanism. Rex Motor Manufacturing Co., Ltd., and H. Sarginson, 816
Cooling Arrangements. Albion Motor Car Co., Ltd., and T. B. Murray, 212
Cycles, Motor. East London Rubber Co. and E. A. Baines, 615
Motor-Car Lamps. S. O. Cowper-Coles, 113
Speedometers. J. B. Hamilton, 815
Spring Suspension. F. H. Royce and Rolls-Royce, Ltd., 688
Steering-Wheels. C. W., F. H., and E. A. Bluemel, 688
Transmission Gear. C. H. Dent and Dent Motors, Ltd., 82
Transmission Gear. Etablissements de Dion Bouton (Soc. Anon.), 340
Wheels. F. and A. Probert, 515
Wheels, Detachable. F. W. Lanchester, 515

Printing and Allied Machinery:
113, 550, 616, 783
Die-Printing Presses. H. B. Croker, 616
Lithographic Printing-Machines. J. Shackleton, 783
Off-Set Printing-Presses. A. H. Walker, H. Pearce, and T. R. G. Parker, 113
Stereotyping. Duplex Printing Press Co. and H. F. Bechman, 550
Type-Casting Machines. G. O. J. Stubbs, 550

Pumps:
113, 443, 480, 550, 616, 688, 783
Air-Compressors. W. Evans and Brecknell, Munro and Rogers, Ltd., 616
Air-Compressors. Mavor and Coulson, Ltd., and J. M. Copland, 480
Pumps. H. A. Humphreys, 443
Rotary Pumps. J. S. Raworth and T. Browett, 113
Rotary Air-Pumps. G. and J. Weir, Ltd., and J. Petermoller, 688
Rotary Pumps. G. and J. Weir, Ltd., and J. Petermoller, 550
Rotary Air-Pumps. G. and J. Weir, Ltd., and J. Petermoller, 783

Railways and Tramways:
113, 152, 212, 340, 480, 515, 550, 653, 688, 752, 850, 880
Anchoring Tramway Rails. Thos. Green and Son, Ltd., and E. Rhodes, 850
Axle Journal-Boxes. E. Peckham and F. S. Andrews, 212
Brake Apparatus. J. N. Curtis and E. D. Sampson, 515
Brake Mechanism. Consolidated Brake and Engineering Co., Ltd., and E. S. Luard, 340
Buffers, Central. Edgar Allen and Co., Ltd., and H. H. Gunstone, 212
Buffers. C. H. Gray, 480
Hopper Wagons. Metropolitan Amalgamated Railway Carriage and Wagon Co., Ltd., and W. H. Wigley, 688
Locomotives. James Howden and Co., Ltd., and J. Howden, 152
Overhead Trolley Wire Construction. Oesterreichische Daimler Motoren A.-G., 516
Points and Crossings. Edgar Allen and Co., Ltd., F. Bland, and E. Larmouth, 516
Points and Switches. H. A. Thomson, 653
Rail-Chairs. F. J. Hadfield, 752
Railless Traction Systems. E. M. Munro and the Railless Electric Traction Co., Ltd., 114
Signalling Apparatus. Siemens and Halske A.-G., 516
Switches, Railway. A. H. Johnson and L. W. Williams, 340
Train-Recorders. Siemens and Halske A.-G., 340
Trains, Lighting, Heating, and Ventilating. J. Stone and Co., Ltd., and A. H. Darker, 113
Tramcar Life-Guards. J. Bowring, 688
Tramcar Life-Guards. J. Whiteley and J. M. Moss, 113
Trolley Bases. E. M. Munro and the Railless Electric Traction Co., Ltd., 152
Trolley-Poles. E. M. Munro and the Railless Traction Co., Ltd., 114
Vehicle Trucks, Railway. Brush Electrical Engineering Co., Ltd., and S. Leech, 550

Ships and Nautical Appliances:
304, 444, 516, 550, 616, 653, 784, 850
Ash-Ejectors. J. Stone and Co., Ltd., and W. S. Parsons, 616

Ships and Appliances—*continued.*
Compasses. Kelvin and James White, Ltd., and F. W. Clark, 550
Compasses, Gyroscopic. Firm Anschutz and Co., 850
Dredgers. Fleming and Ferguson, Ltd., and E. Dunlop, 784
Gyroscope Compasses. Hartmann and Braun A.-G., 516
Log Apparatus, Ships'. Thomas Walker and Son, Ltd., and T. S. Walker, 444
Marine Propulsion. The Hon. C. A. Parsons and S. S. Cook, 516
Marine Propulsion Installations. C. A. Parsons and S. S. Cook, 444
Marine Turbine Propulsion. The Warwick Machinery Co. (1908), Ltd., and S. J. Pigott, 653
Rudders, Ships'. R. S. Bagnall and Sons, Ltd., and C. L. Bagnall, 850
Speed-Indicators. Chadburn's (Ship) Telegraph Co., Ltd., and A. J. Grant, 304
Turbine Installation, Marine. A.-G. Brown, Boveri, 880

Steam Engines, Boilers, Evaporators, &c.:
82, 114, 152, 304, 372, 444, 616, 653, 784, 850
Condensers, Evaporative. E. H. Beckett, 784
Engines, Steam. J. Davidson, 114
Fire-Grates. J. W. and T. A. Thomas and C. Millard, 444
Furnaces, Water-Tube Boiler. Babcock and Wilcox, Ltd., and J. Rosenthal, 372
Generators, Steam. C. M. Shaw, 304
Injectors. H. E. Gresham, 654
Injectors. H. E. Gresham, 850
Scaling Boiler-Tubes. W. H. Cheyne and G. R. Mewburn, 444
Steam-Traps. W. M. Still and Sons, Ltd., E. H. Still, and A. G. Adamson, 616
Superheaters. Galloways, Ltd., and H. Pilling, 304
Superheaters. F. K. Woodroffe and J. C. Blythe, 650
Superheaters. A. F. Yarrow, 114
Surface-Condensers. A.-G. Brown, Boveri, 654
Turbines. Allgemeine Elektricitäts Gesellschaft, 784
Turbines. C. A. Parsons (two patents), 304
Turbines. C. A. Parsons, 444
Turbines, Steam. Warwick Machinery Co. (1908), Ltd., and F. Samuelson, 304
Valve-Gear. J. Davidson, 152
Valve-Gear. J. Davidson and W. O. Larmuth, 444
Valve-Operating Gear. A. Robertson, 616
Valves, Reducing. J. Graham, A. Graham, Jun., and D. A. Graham, 152
Water-Tube Boilers. A. F. Yarrow, 82

Textile Machinery:
114, 340, 654, 688, 784, 850, 880
Beams, Warpers' and Weavers' Beams. W. Pemberton, 784
Calender Bowls. The Bradford Dyers' Association, Ltd., and J. Graham, 340
Loom-Pickers. J. W. Taylor and Y. Yates, 688
Loom-Shuttles. R. Starkie, 340
Loom-Shuttles. J. Tanner and E. Graham, 784
Net and Tulle Machines. A. G. Bally and J. Richard, 880
Spinning-Frames. Jonathan Hattersley and Son, Ltd., H. Peterson, and J. Lee, 850
Spinning-Slivers. W. T. Smith, 114
Threading Loom-Shuttles. J. R. Bradshaw, 654
Weft-Replenishing Looms. B. Crossley, S. Lawson, and the Palatine Automatic Loom Company, Ltd., 114

Vehicles:
654
Fenders, Vehicle. R. J. Marshall and W. H. Penman, 654

NAMES OF PATENTEES.

ENGINEERING.

ERRORS IN CHAIN-SURVEYING.

By Captain J. E. E. CRASTER, R.E.

THE following investigation was carried out in order to ascertain the size of the errors that occur in chain-surveying, and to trace them, as far as possible, to their proper sources. The chain-surveying here referred to consisted of long survey lines, measured across rough country, in all weathers. No special precautions were taken to ensure accuracy or to eliminate errors. Each line was chained once only.

The data for the investigation consisted of 208 lines, chained by forty surveyors. The correct length of each line had been found by trigonometrical triangulation, but was unknown to the surveyors, and in this way the actual error made in chaining each line was ascertained.

A few large errors occurred, and in most cases they were found on investigation to be due to mistakes in booking. In these cases the booking was corrected. The remainder of the large errors were due to unknown and abnormal causes. The inclusion of these abnormal errors would have spoiled the analysis, as it was intended to investigate only the causes of normal errors. For this reason all errors larger than fifty links were rejected. There then remained 196 lines, giving 92 positive and 104 negative errors.

To reduce the data to a form suitable for mathematical analysis, it was necessary to group together all lines of approximately the same length, and to find the mean error of each group. The following statement shows the results of this grouping :

27 lines between 70 and 80 chains in length, mean error 10.21 links.
32 lines between 80 and 90 chains in length, mean error 9.5 links.
23 lines between 90 and 100 chains in length, mean error 10.8 links.
34 lines between 100 and 110 chains in length, mean error 11.53 links.
21 lines between 110 and 120 chains in length, mean error 13.8 links.
30 lines between 120 and 130 chains in length, mean error 13.6 links.

The lines shorter than 70 and longer than 130 chains were too few in number to give a reliable mean error, or to affect the result of the calculations appreciably, and were therefore not included in the subsequent calculations. The errors made in measuring with a chain are of two kinds—namely :

1. Constant errors, due to the chain being too long or too short.

2. Variable errors, due to irregularities in the ground that prevent the chain being laid accurately.

The constant errors, being always of the same sign, will vary directly as the length of the measured line. That is, if d is the difference between the length of the chain and the standard, the error due to this cause in a line n chains long will be $n\,d$.

The variable error made in laying each chain may be sometimes positive and sometimes negative,* and the total error due to this cause will therefore vary as the square root of the length of the line. That is, if f is the variable error made in laying each chain, the total error due to this cause in a line n chains long will be $f\sqrt{n}$.

The final error due to the combination of the constant and variable errors will be the square root of the sum of their squares ; that is, $\sqrt{n^2\,d^2 + n\,f^2}$. Or, if y is the error in a line x chains long, then $y^2 = x^2\,d^2 + x\,f^2$. This is the equation of a hyperbola of eccentricity $\sqrt{d^2 + 1}$ and semi-latus rectum $\frac{f^2}{2}$.

The values of d and f may now be found by inserting for the probable error the mean errors as ascertained from the data, and for the length of the line the mean length of all the lines from which the mean error has been deduced.

Fig. 1. CURVE OF PROBABLE ERROR

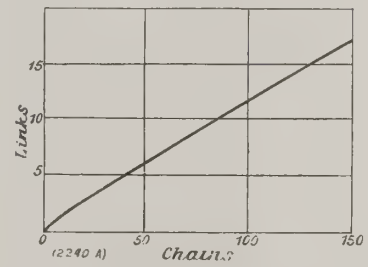

Fig. 2.

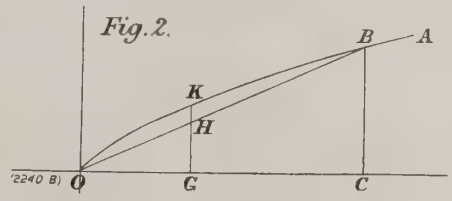

In this way the following six equations are derived from the six groups of lines that form the reduced data :—

$$10.2 = \sqrt{(75.3)^2\,d^2 + 75.3\,f^2} \quad . \quad . \quad (1)$$

$$9.5 = \sqrt{(85.4)^2\,d^2 + 85.4\,f^2} \quad . \quad . \quad (2)$$

$$10.8 = \sqrt{(94.3)^2\,d^2 + 94.3\,f^2} \quad . \quad . \quad (3)$$

$$11.53 = \sqrt{(105.1)^2\,d^2 + 105.1\,f^2} \quad . \quad . \quad (4)$$

$$13.8 = \sqrt{(114.7)^2\,d^2 + 114.7\,f^2} \quad . \quad . \quad (5)$$

$$13.6 = \sqrt{(124.1)^2\,d^2 + 124.1\,f^2} \quad . \quad . \quad (6)$$

It will be seen by inspection that these equations are to some extent discordant, and to obtain the most probable value of d and f it is necessary to solve them by the method of least squares. The weights of the equations are the number of lines from which each has been derived, and are as follow :—

No. 1, weight, 27 ; No. 2, weight, 32 ; No. 3, weight, 23 ; No. 4, weight, 34 ; No. 5, weight, 21 ; No. 6, weight, 30.

Solving these equations by the method of least squares, the values of d and f are found to be :—

$d = 0.108067$ link per chain.
$f = 0.375347$ link per chain.

The value of d, the error due to the chain not being the right length, is a good deal larger than might have been expected. This is probably due to the difficulty of standardising the ordinary steel chain, the length of which can only be altered by cutting out, or adding one or more of the small rings that join the links—a tedious and inaccurate process.

The curve of probable error for lines up to 150 chains in length is given in Fig. 1, annexed, and from it the probable error in any chained line may be determined.

When a chain survey is based upon points the distance between which has been determined by trigonometrical triangulation, as in the case of the Ordnance Survey, the greater part of the chain surveyor's errors can be eliminated. This is done by distributing the error uniformly along the whole length of the line. But even after this has been done, there will be a small residual error, because the surveyor's error does not in reality vary directly as the length of the line. The size of the residual error in any line may be found as follows :—

The probable error in a line n chains long will be $\sqrt{n^2\,d^2 + n\,f^2}$. If this error is distributed uniformly along the line, a correction of

$$\frac{1}{n}\sqrt{n^2\,d^2 + n\,f^2}$$

will be applied to each chain length. But the probable error at any point p chains from the beginning of the line is $\sqrt{p^2\,d^2 + p\,f^2}$, and the correction applied at this point is

$$\frac{p}{n}\sqrt{n^2\,d^2 + n\,f^2}.$$

The residual error is therefore the difference between these two quantities ; that is,

$$\sqrt{p^2\,d^2 + p\,f^2} - \frac{p}{n}\sqrt{n^2\,d^2 + n\,f^2}.$$

This may be represented graphically as shown in Fig. 2, in which O A represents the curve of probable error, a hyperbola of which the equation is $y = \sqrt{x^2\,d^2 + x f^2}$.

The probable error of any line of length O C is represented by B C. The error at any point G is represented by G K, and the correction applied at this point by G H. H K then represents the residual error at the point G.

To find the greatest possible residual error in any line, let us assume that the line O C is infinitely long. The point B will then lie on the asymptote to the curve O A, and the chord O B will become parallel to the asymptote. The greatest residual error that can arise will be represented by the vertical distance between the chord and the asymptote.

The equation for the asymptote is

$$y = d\,x + \frac{f^2}{2\,d},$$

and the equation for the chord is $y^1 = d\,x$.

The maximum value for the residual error is $y - y^1$; that is $\frac{f^2}{2\,d}$, or 0.66 link.

On the Ordnance Survey the greatest discrepancy

* Negative errors generally arise through the surveyor allowing the rear end of the chain to slip forward a little when it is pulled taut.

allowed between the chained length of a line and its length as obtained by trigonometrical triangulation is one link per thousand for maps on scales larger than $\frac{1}{2500}$, and two links per thousand for maps on the $\frac{1}{2500}$ and smaller scales. The limit of one per thousand is less than the probable error, and the residual error can therefore never be as great as 0.66 link. An error of this size is represented by a length of less than one hundredth of an inch on the $\frac{1}{500}$ scale, the largest scale used by the Ordnance Survey Department.

An error of two per thousand is rather less than twice the probable error, and the residual error in this case must therefore be less than 2×0.66 links; that is, less than 1.33 links. An error of 1.33 links will be represented by a length of $\frac{1}{250}$ of an inch on the $\frac{1}{2500}$ scale.

The residual error in every case is therefore too small to affect the accuracy of any of the Ordnance Survey maps.

THE INSTITUTION OF CIVIL ENGINEERS' CONFERENCE ON EDUCATION AND TRAINING OF ENGINEERS.

(*Concluded from page 863 of our last volume.*)

As reported in our last week's issue, the Conference of the Institution of Civil Engineers on Education and Training of Engineers was continued on Thursday, the 29th ult., when the proceedings were opened by Dr. W. C. Unwin, who, at 10 A.M., took the chair at a joint meeting of Sections I. (scientific training) and II. (practical training). Dr. Unwin's opening address is reprinted herewith :—

It has been thought desirable by the Council of the Institution to impose on the chairman of a section the duty of saying some introductory words. I think it may be taken for granted that it is now agreed that engineering training should include scientific instruction and practical and commercial experience. But very divergent views are held as to the relative importance of the different components of such a training and as to the order and duration of each. We must recognise at once that the field of engineering employment is a very wide one, and that different capacities are required in different parts of that field. It is therefore in no way surprising that persons whose opportunities of observation give them every right to express a definite opinion as to what is best for one special branch of engineering have arrived at conclusions very different from those held by others, whose field of work has been in a different branch. No system of engineering training can be arranged to meet all special demands, and it is the object of such a Conference as this to find out what is most essential in all courses of training and what modifications are practically possible to meet different cases.

First of all, I think it must be assumed that the engineering education we are specially charged to consider is that of young men whose aim it is to arrive ultimately at a professional status, such a status as membership of this Institution implies. Their hope is to be employed ultimately in the design and control and direction of engineering work. Of course, some of them may fail in capacity or may lack opportunity, and may drift to one of the many more commercial occupations allied to engineering, and even there the knowledge they have acquired will be a valuable asset. But at the outset a professional career is aimed at, and the system of engineering education must be arranged to meet that condition. It is probably only by educating many that the few can be found who have the capacity and character necessary to achieve considerable advances and to do work of national importance.

Now, very few young men at 18 can foresee into what line of employment they may be driven, and consequently the first or undergraduate stage of education must be broad, so as to fit students as far as possible for widely different spheres of work.

Perhaps the greatest defect of engineering education at present is the want of more provision for the higher and more specialised education of the few students of real capacity, discovered in the sifting process of an undergraduate course.

In spite of the general acceptance of the view that a study of scientific principles and their application is a necessary preliminary to a practical course in field or workshop, a certain jealousy of college education is still obvious in some practical engineers. While conceding in words that some scientific education is necessary to an engineer, they would in fact confine it to very elementary matters. They would greatly restrict the time given to it, and they are disposed to depreciate the value of any higher teaching, and even to regard it as mischievous and likely to unfit a man for the strenuous life of the manufacturing workshop.

I believe the idea that a college course unfits a man for practical work is a wholly mistaken one. There may be students who prove unfit for practical work in spite of college education. They would equally fail if their education was purely practical. There may be college courses, I am afraid it must be said there have been college courses, badly arranged, and teachers in colleges less competent than is desirable. But such things are inevitable. Nothing is more certain than that there has been a great improvement of college teaching of applied science in the last 20 years.

An employer who takes into his works college students is, I think, often disposed to expect from them an immediate availability which is unreasonable. It is not the main object of a college course to make a student acquainted with the details of any particular business; that is the proper object of the first year or two of practical work. It is not the main object of a college course to fit students specially for such work as will fall to them while in the lowest rank of the profession. The college course must contemplate the fitting of a student for his whole career and provide him with an intellectual equipment which will only gradually become useful as he rises to higher rank in his profession. The view of the employer who looks only to the immediate usefulness of the student is a shortsighted one.

Nevertheless, a college course is an unpractical and badly designed one if, at the end of it, a student is not more capable and useful from the first, in any type of workshop, than a lad without such a training. The college discipline is bad if he has not much more character and energy than the raw lad. His training has been a failure if he does not pick up the specialised details of any business to which he may be put far more rapidly than an untrained lad. I should like to suggest to those practical engineers who are implicitly, if not openly, hostile to college training, who would, at an rate, greatly restrict it, and who advocate lenghtened periods of workshop apprenticeship, that they exaggerate the value of such workshop experience as an ordinary apprentice gets. I am not, of course, considering the artisan apprentices who have to learn handicraft, but young men expecting to rise to positions of trust. Here and there are works where special trouble is taken with apprentices; but in general apprentices are left to pick up what knowledge they can with very little help, and in many cases, I think, a good deal of their time is absolutely wasted. Some skill of handicraft is no doubt acquired. But the engineer works with his head, not with his hands, and manual skill is of use to him only in exceptional cases.

I hope I do not in any way underrate the value, to mechanical engineers especially, of that kind of knowledge of materials, of tools, of processes, and of cost, which can only be learned in the workshop. But I think practical engineers forget how little of this valuable knowledge really comes to the works apprentice. The engineer of higher rank, who discusses matters with foremen and draughtsmen, who has responsibility for design and cost, and who is in a position to know the reason of all decisions, is learning in the workshop all his life, and naturally sets a high value on the knowledge slowly acquired by years of constant and close observation. So high a value that perhaps he ignores the importance of the scientific knowledge which was, somewhere and by some one, applied in bringing his business to a state in which it can be carried on successfully as a mere manufacture. But the knowledge which comes to those in responsible positions is not open to the ordinary apprentice, and he learns slowly, if at all, unless he brings to the works such a knowledge of principles and methods that he can interpret for himself what he sees. No system of workshop apprenticeship can, I think, be considered satisfactory unless someone is specially charged with care of the apprentices, whose duty it should be to make sure that they have opportunity of seeing a great variety of work and of helping them over their difficulties.

I believe employers will find—some of them have found already—that they owe a debt to the colleges, and that the college-trained student will prove, with a minimum of special experience, a valuable assistant, and in some cases the originator of real advances in practice. I should like to plead that in return the employer might be a little more ready to give college students a year or two years' run of the works, either without remuneration or with a small remuneration, just enough for disciplinary purposes. I do not think there would be any loss in the case of a properly trained student, and the employer would in many cases find an assistant worth keeping and promoting.

The subject down for discussion at the joint meeting was, according to the programme, "the relation of engineering employers and colleges from the point of view of the practical training of engineers." This was opened with two prepared contributions, one by Professor J. E. Petavel, and the other by Mr. J W. Horne. These we reprint in full on page 41 of the present issue. Professor Petavel elaborated a few of his points during the reading of his contribution. He drew attention to the fact that there were three alternatives to choose from. In the first, works training came before college. One objection to this was that a boy, in works, found it difficult to keep up his book-work sufficiently to keep pace with others when he returned to the college, but a second was that the lad lost touch with the employer whose works he had been through. Such a break necessitated a fresh start after college, and that was a handicap. In the second system practical training came after the college. To this there was the objection that the boy by that time was so old that he was not able to get into close touch with the men. The third was the sandwich system, to which one objection was that employers in some cases were not willing to concede the necessary privileges the system involved, as partial employment of the kind upset works routine, while, on the other hand, college courses were arranged for three years. The latter point could be altered; but if engineering students were a class apart, they would drop out of many valuable parts of university life, which, with a session different to that of the other students, it would be impossible for them to join. He pleaded for a broad college training, as it was impossible to foresee what work youths might ultimately turn to. He thought a laboratory convenient in that it brought together many typical machines from which the student might acquire a variety of knowledge which it would be hopeless for him to try to acquire in shops, as that would necessitate a training in 10 or 15 different works.

The Chairman first called upon Mr. Alexander Siemens, who spoke from the point of view of the employer. Manufacturing was carried on, he remarked, not for amusement, but for profit, and it was not practicable in many cases to arrange to take pupils. At the works of his firm they took them when they had vacancies, but it was impossible for them and for others to promise to take a definite number each year. They could not, under any circumstances, take lads who wanted to be away from the shops one or two afternoons a week. Such lads had better stay away altogether. He would remind the meeting that the Commissioners of the 1851 Exhibition had recently instituted bursaries for the purpose of assisting the completion of courses of engineering training in suitable cases.

Professor G. Kapp, with regard to the reference to these bursaries, said that in Birmingham maintenance and scholarship money was now given to lads worth educating. He supported the sandwich system, to which the chief objection was that ordinarily the slices, so to speak, were too thin. The usual college vacation was so short that, after a few days' rest after the examinations, there remained less than three months available for the shops. However, even under these conditions, they found some employers willing to take the lads. Offers were received from firms to take good boys, and such lads would profit, and return to their college work in a much more receptive and appreciative mind. In Scotland the six months' system was feasible. That was better, but was not applicable here, as college life could not be changed for one class of students. He thought the case might be met by a twelve-monthly scheme, or, rather, one year at college and fourteen months in the shops, extended far enough to give a four years' course at college. The lads should, of course, always return to the same works, as the employers thus had an opportunity of sifting out the lads, and at the end of the time the good lads would be able to fill positions of usefulness.

Herr F. zur Nedden said he was moved to speak by Sir William White's reference to Continental methods of training. In 1899 a committee had sat on this subject in Germany, and had come to several conclusions, which they were now, after twelve years' experience, in the act of reconsidering. The first point on which a decision had been reached in 1899 was that one year should be spent in works before the college training was taken. That had worked well on the whole. Secondly, a code of rules had been drawn up, regulating the training to be given in factories; these were, as nearly as was possible, similar to the rules recommended by the Institution of Civil Engineers' Committee of 1906, and were in Germany still adhered to. Thirdly, a list of suitable works had been drawn up—some 500 or so—at which students would be taken and educated in conformity with the code of rules. The last feature had given trouble. Employers would sign the contract required, but in practice found themselves unable to keep to the ideal, because business matters necessarily interfered. Universities had money to expend on salaries, but factories had not, and they could not make efficient arrangements for teaching. The thing had to be on a paying basis. Dividends were so important that the works manager had to consider current expenses. It appeared that the Revision Commission now sitting would probably decide that premiums should be allowed, and that wages could be paid out of this; also that, in additional return, the manufacturers should be bound to encourage the acquisition of knowledge by the students, either by supporting evening classes, providing teachers, libraries, &c. That the student, in return, should take the whole of his practical training at one factory, and would remain there

after finishing his college work for at least six months, in order that the employer might have the opportunity of selecting and engaging such men as might prove of value to him.

Mr. J. F. C. Snell thought it better that the students should proceed to college first, and then to works. There was then no break in theoretical work. The sandwich system was only a compromise. At 22 years of age, after college, a boy would be better able to absorb workshop information than would a raw youth of younger years. The profession had become highly developed, and after college a lad would prove more valuable to an employer. He would be able, for instance, to measure and take observations accurately. He thought insufficient attention had been given at the Conference to the service of drawing-office experience, which really was invaluable. The Institution would do lasting good if it appointed a sectional committee to take up this matter of education and work with the colleges, &c.

Mr. B. Hall Blyth, speaking as a civil engineer, reminded that engineering works and offices were kept open merely for profitable work, and not for educating pupils. He strongly disapproved of the attitude held by some professors that college training fitted a boy to occupy a salaried position in works. Even at the end of four years' practical training there was still much to be learnt, and a college student could not hope to take an active part in work until he had had practical experience.

Professor Wertheimer thought that very few, if any, professors actually held the view just attributed to them by Mr. Blyth. He wished to point out that at Boston, at the Massachusetts Institute of Technology, the boast was made that a post was secured for every student before he left. That was not so here generally, and the fault perhaps lay with the training here. However, at Bristol they had fortunately arrived at such a state. They had had difficulty, but it was past, and now they had more applications for lads than they could supply, employers frequently asking for a lad similar to such or such a one who had gone to them before from the college. He thought that, generally, the engineering students were not discouraged sufficiently. It was for the good of the youths that this should be done. They did not keep all their first-year students in the second year. Parents were advised to withdraw lads who seemed unsuited to the career. For the capable artisan they provided either a long course of evening study leading up to the degree, or scholarships enabling artisan students to stand the risk of leaving work to attend college courses. Bursaries were granted sufficient to support them till they returned to their ordinary avocations.

Sir W. White remarked that the needs of Canada and the United States were so different that no inference could be drawn from Professor Wertheimer's allusion to students over there. Young men trained here could equally well get work over there, provided they did not set employers against them by their conceit in book-work. At the very earliest possible moment it was essential to find out whether a lad had aptitude for an engineering career. Men who could do anything in the way of book-work were often quite unfitted for active engagement in engineering work. He recommended that the first year after school should be spent in works. He thought it obvious that if any lad was to receive teaching anywhere, it must be paid for, and it was right that the employer should be paid, unless he set himself up as a philanthropist, when he probably would not last long.

Mr. H. J. Spooner said he would welcome any step which would bring polytechnics, &c., into closer touch with the colleges. He thought college workshops gave relief to the mental strain, and a lad could learn things in a college workshop which would fit him better for the shops afterwards—for instance, accuracy of measurement, so important now in gauge-work, or the principles underlying machines such as gear-shapers. In some shops the man with a slide-rule had been usefully employed tuning up and increasing the speed and output of tools.

Professor S. P. Thompson had never found engineers openly hostile to college training as Dr. Unwin had suggested. They were eager to get men so trained. He preferred students who had had one year or more in the works. They were more receptive, and had a better idea of the proportionate value of what they were being taught. The six months' system was impossible. At Finsbury they had a two years' course, which could be extended if desired, but which was short enough to be interposed, if necessary, between school and work, or taken afterwards, if desired. Working up specially for degrees was not encouraged.

Mr. W. Patchell pointed out that, for a lad to learn what was worth learning in the shops, he should not be a supernumerary in a gang, such as he would have to be if he attended works for short periods or broken time. That was demoralising to the lad. He must be a useful hand. If present funds were better spent, he thought there would be money enough to deal with the question properly. Instead of poorly educating the mass, more care and money should be spent on those worth educating.

Section II.—Scientific Training.

This section met at 11.30, in the library, under the chairmanship of Dr. W. H. Maw, for the discussion of Professor S. M. Dixon's and Professor C. F. Jenkin's communications dealing with the value of a university degree in relation to professional competence. These communications, which were read by their authors, are reprinted on page 39 of this issue.

The Chairman, opening the discussion, said the paper which had just been read stated very clearly and, he thought, impartially the advantages which might be expected to accrue from the attainment of a university degree in engineering science. The authors were both men of experience, thoroughly acquainted with the work which a university degree entailed, and they both expressed their belief in the good influence which that work would exercise on the future career of the engineering student. He would say that that belief would be very generally shared by those who had considered the subject; but the object of the present Conference was not so much to indulge in beliefs or expectations as to evolve definite information as to facts, and he hoped that in the discussion they might be favoured with the experience of employers and employed as to the real value attached to university degrees in works and offices. It had been sometimes urged that the possession of a university degree should entitle its holder to at once receive, on entering an engineering works, a higher emolument than would be accorded to him if he did not possess such a degree; but from this view he strongly dissented. The commercial value of a young engineer to his employer depended upon a number of qualifications, of which many were in no way connected with his college work, and it would be unreasonable to expect any employer to take the possession of these qualifications for granted simply because a man had obtained a degree. But if the work through which a student had gone to attain his degree was sound, it should serve him in good stead in his practical career, and he might fairly be expected to advance more rapidly than one who had not had a similar training. If this result did not follow, then something was certainly wrong, and the sooner the reason was known the better. The fault, if it existed, might be due to defects in the training for the degree, or might arise from the fact that the period occupied in that training had rendered the student less receptive of the teachings of workshop practice. On this and many other points he hoped that information as to the result of practical experience would be forthcoming in the discussion.

Professor J. E. Fleming said that he was afraid he must advance some unorthodox views. He thought the value of university degrees, as they were at present awarded, was very small. There was nothing to be gained by ignoring facts, and it must be recognised that degrees were obtained as a result of written examinations held against time, and to be successful in which a man had to rely almost entirely on his memory. These conditions were entirely artificial, and corresponded in no way with the conditions met with in practical life. In practice one did not usually work against time, and did not rely entirely upon one's memory. The most useful memory was that which remembered where to find information, not that which simply amassed a quantity. The result of the examination system was that a degree was no criterion of the practical value of the man who possessed it. Candidates in general made far too much of the value of a degree in itself—of the mere letters after their names—and lost sight of the work the degree was supposed to indicate. Practical men thought nothing of degrees, and did not care if their assistants could write half the alphabet after their names. What they demanded was reliability, ability to reason, and accuracy. Some of these qualities could only come as a result of experience. He thought the whole examination system wanted turning inside out, and would like to see much more attention paid to *vivâ voce* work and practical examination. He would like to see the degree system abolished altogether.

Mr. Dugald Clerk said that he spoke as an employer. His experience of B.Sc. men was not so unfortunate as the remarks of Professor Fleming might have led one to expect. He had five men holding B.Sc. degrees in his London office, and they were all in every way practical, and were able to apply their theoretical knowledge in every-day work. He was not so sure, however, as to the place of a man with an engineering degree in a works. At the factory of the National Gas-Engine Company, at Ashton-under-Lyne, they had no B.Sc. men. It should be remembered that the evening classes of this country supplied a large amount of theoretical training, and he thought the class of men who made good works managers very largely received their technical education at them. There were some 700,000 students attending evening classes in England, as compared with about 13,000 in Germany, and the scientific knowledge which was required in workshops was very largely supplied, in England, from these classes.

Mr. A. P. Trotter spoke neither as an employer or a teacher, but as one who had some connection with the University of London. He had sat for eight years as a member of a board of studies for that University, but had always protested against the establishment of a degree in engineering. He did not believe in such things. Degrees should be given for theoretical work, and for things which could be taught at colleges. A degree in engineering or mining was an absurdity. Universities should confine themselves to fundamental principles which they could teach. Engineering could be learnt only in practice, and if universities attempted to deal with practical subjects, such as switchboard design, all they taught would be out of date in three years. We had heard much about university men in practical life in America, but he thought that up to recently the American system had mainly succeeded in producing a remarkable crop of swelled heads. Matters had, however, improved somewhat of late.

Colonel B. R. Ward, the next speaker, said that he noticed both Professor Dixon and Professor Jenkin laid considerable stress on the value of a good general education in students. His experience as a teacher of cadets entirely bore out this idea. He thought it absolutely necessary that students should be well instructed in what the Germans called "knowledge" subjects, such as history. What he might call the dead matter of engineering was, in fact, only half of engineering, and to enable anyone properly to apply that half, it was necessary that they should have a good education on the literary and general side.

Mr. James Glover agreed with Mr. Trotter that universities should carefully avoid attempting to teach the details of engineering, and should confine themselves to the principles. An important reason for this was that it was only while men were young that they could properly assimilate the principles. Later in life, when they were earning their living, they had no difficulty in learning any amount of technical detail; but if they did not grasp principles early, they were likely never to grasp them at all. He was not in agreement with Professor Fleming's somewhat contemptuous view of the value of degrees. When choosing among a number of men he would always be inclined to give preference to those having degrees of any kind. A degree at the lowest always stood for a certain amount of work done.

Professor Silvanus Thompson disagreed from the last speaker, who evidently thought that a degree had a face value. He had one of his own that was not worth sixpence, and never had been. The belief in degrees *per se* was a national failing. We were suffering from the curse of running after degrees simply that we could stick the letters after our names. Too many young men thought of degrees only from this point of view, and cared nothing for the work that the degree was merely an index of. In general estimation the Associateship of the Royal School of Mines was of less value than a B.Sc., but in reality it was of ten times the value. The same thing applied to the diploma given by certain colleges.

At this stage of the proceedings the discussion on Professor Dixon's and Professor Jenkin's papers was terminated by a vote of thanks to the authors, and after Dr. Maw had retired from the chair to make way for Professor Unwin, the three papers on "The Position and Uses of Engineering Laboratories in Relation to Education at College," by Professors W. E. Dalby, John Goodman, and Bertram Hopkinson, were read by their authors. These papers are reprinted on pages 40 and 41 of this issue.

The discussion on the second subject was opened by Mr. R. S. Ball. He began by saying that he agreed with Professor Hopkinson that laboratory apparatus should not be too complicated. He had been at the Massachusetts Institute of Technology for some years, both as a student and a teacher. They had there the best-equipped engineering laboratory in the world. It contained, among all manner of devices, a 200-horse-power triple-expansion engine, in which some twenty students were required to run a test. He thought experimental work of that order was much less valuable than work carried out on smaller and simpler apparatus, on which the students might possibly have to do their own erection. There were 1600 students at Massachusetts; but even in big colleges like that he would prefer to multiply the examples of simple apparatus rather than instal large and complicated machines. On the general question of the value of laboratories in engineering colleges, his opinion might, perhaps, be expressed in the remark of the Irishman, who thought the ocean was a great aid to navigation.

Mr. Dugald Clerk agreed that very much might be done with simple apparatus in laboratories. It was better that a student should have complete control of his own experiment rather than that he should simply take some small part in a large and complicated test. The difficulty with laboratory machinery was that it quickly got out of date, and in some cases manufacturers had loaned modern machines to colleges on the understanding that they should have copies of the reports of all tests carried out. The system was an excellent one for the colleges.

The Chairman, in closing the discussion, said that while it was possible to do very valuable work with small apparatus, it was desirable to have large apparatus in addition. If students were at times engaged on tests of a large engine. they got a much better idea of the scale of practical work than if they spent all their time with quite small machines. A twenty-four hours' trial run of a large engine was an education which students could never get when experimenting by themselves on a small scale.

Section III. (Practical Training).

The remainder of Thursday morning was occupied, so far as Section III. was concerned, with two discussions, which, like the others, did not keep very closely to the subjects chosen. The first was on "The Relation of Practical Training to College Study: whether, or to what extent, before, sandwiched, or after its conclusion." This was introduced by Professor Archibald Barr and Professor H. Louis, though in the absence of the latter that gentleman's contribution was read by Professor Welch. These contributions are reproduced on page 42 of this issue.

The first speaker at this meeting was Mr. H. Rolfe, who pointed out that the requirements of civil and mechanical engineers were totally different. One was concerned with fine work, accurate measurements and fits, interchangeability, &c., which did not enter in the same degree into the civil engineer's work. He would lay stress on drawing-office work. College students failed in designing things on scientific lines alone, not taking into account all the other important factors which influenced the subjects, such as pattern-work, machining, &c. Colleges should recognise these facts, as machines, &c., had to be made for a profit. Mathematical correctness of design might not be able to compete when it came to early delivery and other commercial factors. He was pleased to see that Sir Frederick Donaldson recommended foundry work, forging, and pattern-making at the Arsenal course; without knowledge of these a man was poorly fitted for his work.

Mr. W. B. Worthington said no rule could be laid down to meet all cases, and there was nothing to be gained by standardisation. He thought a boy who was to become a structural engineer should attend college first and then start on his apprenticeship. When going into an office a lad was soon put on structural steel work in order to familiarise him with design. Much of the principle of design could, however, be better learnt in college, and if drafted straight to an office he would waste time there acquiring laboriously mathematical knowledge which could be more quickly obtained at college. He assumed, of course, that the lad would have been given one year of shops first, in either case. To the mechanical engineer the sandwich system was comparatively easy. Work of the kind then encountered was more easily broken off; but in civil engineering a lad might have to break off right in the middle of a job, and on returning find it finished, and would then have to start afresh with something new.

The next speaker was Professor Turner, who supported Professor Barr's plan, but for other reasons. No solution had been reached after 25 years of discussion of this subject because conditions varied to such a degree. The college student required enough knowledge of the shops to be able to appreciate the training value of theory, and conversely with the shop lad. The ideal system could only be followed where every facility was obtainable, and money little object. Under such conditions, he had trained several lads on the three months sandwich system, which had answered admirably. The system was only suited to special cases.

Sir A. Binnie considered that while engineering training had improved, the results were not satisfactory, and the preparation of youths did certainly not fit them for appointments Colleges should have more consideration for their students. Going into a workshop was not civil engineering. Men went out into the world knowing nothing of their profession or its history, of which they themselves had to continue the development. They were narrow-minded, and even mechanical. He would like natural philosophy, as the words were used in their old sense, to be more studied; he wanted a civil engineer to have a knowledge of geology and physiography. He found classical reports and names unknown to candidates he had come in contact with, while there was a considerable degree of ignorance of surveying and the outdoor use of instruments. A man should go to college and get as broad a knowledge as possible. Practical ability was not always necessary. A bridge designer need not be able to do riveting; it was sufficient if he knew what could be done and when it was well done. Colleges should help to fit men to go out into the world. He recommended the study of the difficulties and influences which former engineers had to contend with on large works of which there were so many at hand at home, and better experience would be gained in this way than in time spent in shops.

Colonel Sir E. Raban thought more care should be taken of the average man. The best would care for himself, the worst would, in any case, drop out. He pleaded for a wide general education which developed a receptivity of mind. Men should have a broad grasp of affairs; it was not sufficient to turn a man out an engineer alone. As a constructional engineer had not time to learn everything, it was not possible for him to go through a mechanical course. College laboratories and workshops might be of assistance in such circumstances by giving men some idea of the mechanical side. He thought it impossible to work the sandwich system here, though it was easily possible in Canada, for instance. Some of the men filling the middle grades could well be left to do their own work in the best way possible, and a man with a receptive mind could pick up from such men valuable information of service to him. Attention to the administrative aspect was important, and colleges might give to their students a few indications along these lines. They always insisted on a man passing some time in the head office, where much was to be learnt; for instance, how it was letters could not always be answered the same day. The most important needs were that all should rest on a sound general and not a specialised education; that, if possible, university training should be included, that was, scientific training, with, perhaps, sufficient practical work to appreciate facts; that the men should be got out on to works of the kind they hoped to concern themselves with chiefly, as soon as possible.

The meeting then proceeded to the discussion of the subject of "Workshop Training as a Preliminary to Practical Training in other Branches of Engineering." This subject was introduced with prepared contributions from Mr. J. A. Brodie, Mr. J. M. Moncrieff, and Professor J. J. Welch. These are reproduced on pages 43 and 44 in this issue, but as the time was short, they were taken as read at the meeting. The first speaker was Mr. J. M. Moncrieff, who treated the subject from the civil engineer's point of view. There existed among engineers no attitude of jealousy towards college training, in proof of which assertion he stated that he had that morning come direct from the examination-room. Professors did sometimes think their students qualified to take up salaried positions. He had known cases of degree men applying for posts as assistants. They should not think of such a thing until after they had had practical work, and professors should help to dispel any such notions. They were no good without practical experience, and the age should not be more than twenty-two or twenty-three before they got it. Men could not learn everything, and training had to be kept within certain limits. Practical and commercial influences were non-existent in colleges, and could only be appreciated in actual work.

Mr. Gerald Stoney thought it desirable that the lads should come into close contact with the workmen, and feel the effect of the discipline of the shop. Not everyone could be made an engineer. His firm gave pupils great latitude, and allowed them thick and thin slices on the sandwich system, so that between sixteen and twenty-one years a lad could get three years' works and three sessions at college. Only 3 or 4 per cent., were permitted, however, to do this. If the proportion were larger the scheme would be unworkable.

The next speaker was Mr. C. W. Darley, who believed in college training, but thought that the sooner men got out on to work the better. Especially was this the case with men going out ultimately into the Colonies. Such men needed a great deal of experience before going abroad, because, in many of the Colonies, most of the work was done nowadays by day work, under the engineers themselves without the intervention of a contractor. Three or four years' practical training in England were at least necessary before going out. It would be found that most of the papers read and discussed before the Institution were by men very few of whom had had the advantage of a university training.

Mr. R. J. G. Reid followed, remarking that the papers opening the discussions made insufficient distinction between the needs of civil and mechanical enginers. In the case of mechanical engineering if the boy were to take his works training on leaving school he thought the lad should go first for one year into an engineer's office to find out what there was to be learnt. In the case of civil engineering, college should come first, followed by the office, but the term of apprenticeship need not be so long now as formerly. While he was articled he needed more technical knowledge than he could get in the office, and, therefore, attended evening classes. That need had now been filled by the colleges, and these can prepare the lads with knowledge which would be serviceable to them in the office.

Mr. Walter Hunter thought the speeches showed the Conference had been justified. He wished to read a statement in a letter from Mr. C. Mayne, municipal engineer, Shanghai, to the effect that, in his opinion, the English system of training turned out better men, with theory and practice better balanced, than either the American or Continental systems. The latter especially suffered from too much theory and too little practice.

The Chairman, Mr. Elliott Cooper, then closed the meeting of Section III. with a few general remarks on the discussions. He thought it manifest that detailed instruction could not be given in every branch with the idea of training for some possible future work. Civil engineers certainly needed some mechanical knowledge, but it was sufficient for them to know good and bad work. It was not necessary to make a mechanic of a future civil engineer. What was wanted in men going abroad was sound general engineering and scientific knowledge which would fit him for any post. All countries differed, and men could not be taught this variety of information. The local knowledge he found was nearly always picked up quickly. Nowadays engineers were no longer anxious to take pupils. Work was so specialised that they could not give an all-round training. Lads therefore go straight to contractors. Departmental work did not give such experience as a contractor's office did, but the latter must be a large one to afford good training. If the contractor was merely carrying out the work for engineers, a lad lost one most important part of the training. With regard to the sandwich system, he thought it better that for civil

engineers college should come before the practical training. Their work could not be dovetailed sufficiently to ensure a continual progress. College work was intended to familiarise men with the principles of natural philosophy, and going into works first rather spoilt the lad's appreciation of the facts then put before him. It might be possible to get in some practical training, however, but to break off the course of either one or the other was bad.

CONCLUSION OF THE CONFERENCE.

Shortly after 1 P.M. all three sections assembled in the theatre, and Mr. Alexander Siemens again took the chair. Mr. Siemens first called on Mr. A. F. Yarrow, who submitted that the Council should give its attention to the following :—

1. That the Council of the Institution be desired to use its influence in any way deemed practicable to secure a continuity of study between those public schools where the elements of science are taught and the universities and technical colleges, so that pupils leaving such public schools be suitably trained to follow at once a college course with advantage, so that, as it were, the college course may begin where the school training finished.

2. That, with a view to facilitate the above, a closer connection between the masters who teach science in public schools and the Institution of Civil Engineers is desirable.

3. That the Council of the Institution should endeavour to induce the universities and technical colleges to adopt such terms of study—say six months during the winter—so that the "sandwich system" can be adopted, if desired, which is not possible with the terms now customary.

4. That it is desirable that the Council should endeavour to produce some co-ordination between the colleges and the employers by making a systematic inquiry from the employers as to the conditions under which exceptional students, properly qualified, may be able to get practical training for a period of, say, 24 to 36 months on the "sandwich system" or not, when vacancies in such establishments occur.

Mr. Yarrow's proposals were not put to the meeting, but the President said the Council would take notice of them. With regard to general impressions of the Conference, the President said that gentlemen on the scholastic side complained that they were at a loss to know what they had to prepare the boys for. That, he thought, was probably their fault. He would remind them that some six years ago the Board of Education had tried to introduce the adoption of a standard examination, but the scheme came to nothing, because the schoolmasters could not agree among themselves as to what the syllabus should be. Perhaps another attempt might be made now. Recently at a surveyors' conference a syllabus had been successfully drawn up showing the qualifications which would allow a man to practise anywhere within the Empire. With regard to training he thought it bad to specialise too soon. University teaching should be scientific and wide in scope ; the student should be taught how to learn. Students, he thought, could not make proper use of laboratories unless they possessed some practical knowledge. After passing an examination lads should go for one year to works before college, taking more works experience, of course, again later.

In concluding his remarks the President expressed the thanks of the Conference to the Staff of the Institution, and to the Hon. Secretaries, whose labours had contributed so largely to the success of the meetings.

THE ROYAL AGRICULTURAL SOCIETY'S SHOW.

(Concluded from page 853 of our last volume.)

STEAM-ENGINES.

THE general arrangement of steam-wagons and steam-tractors has now become pretty well standardised, and it is therefore impossible to say more than that vehicles of these types were exhibited by Messrs. W. Tasker and Sons, Limited, of Andover, Wallis and Steevens, Limited, of Basingstoke, William Allchin, Limited, of Northampton, and Fodens, Limited, of Sandbach, Cheshire. We may note, however, that a new type of self-tipping wagon was shown by the Yorkshire Patent Steam-Wagon Company, of the Vulcan Works, Hunslet, Leeds. The special feature of this machine is that the body is mounted on small wheels running on slides, and can be traversed by a screw in a fore-and-aft direction over its frame. In the running position the wagon is supported by the frame from end to end, but for tipping purposes it is run back by the screw so as to overhang the frame, and it can thus be easily tipped. The wagon, in spite of the tipping feature, has therefore a long wheelbase, and is yet not abnormally long over all, when the body is screwed home into its running position.

A well-finished compound tractor with springs to both axles was shown by Messrs. Ransomes, Sims, and Jefferies, Ltd., of the Orwell Works, Ipswich. Full-sized traction-engines of the traditional type were also included amongst the exhibits at this stand. Of these, one was fitted with compound engines, and had its rear axle spring-mounted, enabling it to traverse rough roads at a reasonable speed.

OIL AND GAS-ENGINES.

Messrs. Davey, Paxman, and Co., Limited, of Colchester, show as their principal exhibit a gas-engine capable of developing 30 brake horse-power when running on producer-gas. Details of this engine are illustrated on page 6, Figs. 18 and 19. The producer used is of a new type, which we hope to describe later. The most interesting feature of the engine is the arrangement of gas and air-valves now illustrated. The air-valve spindle passes through the spindle for the gas-valve. Whatever the load on the engine, the air-valve always opens fully, but the opening of the gas-valve is controlled by the governor through the agency of a slotted lever. This lever is always rocked through the same angle by the link which actuates it, but the link which connects it with the gas-valve spindle can be shifted from one end of the slot to the other. When this shifting link is at the end nearest the fulcrum of the slotted lever, the gas-valve remains wholly closed, and when at the other is fully opened at each suction stroke. The position which this link occupies in its slot depends, however, on the governor, which can thus adjust the amount of gas admitted in exact proportion to the load on the engine. The engine has low-tension magneto ignition. The cylinder water-jacket is cast in one piece, and is fitted with a loose liner of hard close-grained metal. The lubrication of the working parts has been carefully considered. The main bearings and camshaft bearings are fitted with chain lubrication, consisting of chains which run in an oil-bath, and carry the oil on to the shaft, where it works along, and is finally thrown off at the ends, and led back to the oil-chamber again. The cylinder is fitted with forced lubrication, and the large and small ends of the connecting-rod are provided with sight-feed lubrication, the large end getting oil in the usual manner through the crank-pin, and the small end from a lubricator mounted in front of the liner. The levers and exhaust-valve are also fitted with lubricators. Only one cam is used to operate the exhaust and inlet-valves, and there are thus no overhung rollers. The roller on the exhaust-lever runs in an oil-bath, and carries a film of oil to the cam, and thence to the inlet-valve roller, thus minimising the wear on these parts.

Leyland Motors, Limited, of Leyland, Lancashire, exhibited three petrol-driven lorries, of different patterns. The largest weighs 5 tons, and is fitted with a four-cylinder engine capable of developing 40 horse-power. There are four speeds forward and a reverse, and the wheels have solid-rubber tyres, and are driven through double reduction gearing running in an oil-bath. An exhibit of a similar character was made by Messrs. J. and E. Hall, Limited, of Dartford, who show a 4-ton and a 5-ton petrol chassis.

The Eagle Engineering Company, of Warwick, showed in the "New Implement" class a 3½-horse-power petrol-engine. In this case the cylinder is fitted inside the water-tank, and thus consists of a mere liner only, which can readily be removed for inspection, if desired. The engine has high-tension magneto ignition, and is fitted with two fly-wheels.

Messrs. Petters, Limited, of Yeovil, Somerset, showed, in addition to their well-known ordinary oil-engines operating on the Otto cycle, two new two-cycle engines. Of these, one is mounted on wheels, and the other is a fixed engine. The crank-chamber serves as the air-compressor, the spent gases being blown out through a side port, when a second port communicating with this crank-chamber is uncovered by the piston. The oil-charge is forced into the cylinder at the end of the compression stroke, so that none can escape through the exhaust port, thus avoiding a frequent source of loss in two-cycle engines. The engine will run on crude oil, and a high economy of fuel is claimed. Forced lubrication is fitted both to the cylinder and to the crank-shaft, the oil supply to each being independent of the other.

Messrs. Barford and Perkins, of Peterborough, had on view one of the petrol-driven road-rollers which was fully described and illustrated on page 347 of our last volume. These rollers, we learn, are now made up to 14 tons in weight, and the ease with which they can be started up and despatched with a supply of repair material to a bad spot on a road is found to have a very favourable effect on the cost of road maintenance. As a "new implement" the firm are also exhibiting a light roller having rolls of riveted steel plate, which can be water-ballasted. This roller is fitted with a two-cylinder Aster engine, furnished with high-tension magneto ignition.

The extreme handiness of the small petrol-engine is reflected in the increasing number of them exhibited year by year at the Royal Show. It is worthy of notice that low-tension magneto ignition seems to be the favourite with the engines of this type of American origin, whilst here the high-tension system is preferred. The American engines, too, are very frequently governed on the plan of holding open the exhaust-valve, whilst here it is more usual to prevent the inlet valve opening. This latter plan, however, involves the use of mechanically-operated inlet valves in place of the more cheaply constructed automatic valves.

A very conveniently-arranged small petrol-electric plant was shown by Messrs. R. A. Lister and Co., Limited, of Dursley, Gloucestershire This was entered in the "New Implement" class, and received the award of a silver medal. The plant consists of a petrol-engine driving a small continuous-current generator, which feeds into batteries. The latter, however, are of very small capacity, their principal function being to render the plant self-starting. On switching on the lights, the generator automatically begins to motor the petrol-engine round, which is thus started, and then drives the generator, so that no heavy continuous demand is ever made on the batteries. When the lights are switched out, the engine stops either at once or as soon as the battery voltage is raised to a predetermined limit.

Messrs. Capel and Co., of 168, Dalston-lane, London, N., showed a variety of petrol-oil and gas engines. Two of these exhibits were entered in the "New Implement" class, the one being a self-contained petrol-electric generating plant, with the engine and dynamo mounted on the same bed-plate, whilst the other was a portable suction-gas plant rated at 14 brake horse-power, and this we illustrate in Fig. 20, page 7. The engine is of the builders' standard pattern, the cylinder having a liner independent of the main casting. Forced lubrication is fitted to the cylinder, whilst the crank-shaft has ring oilers. The gas plant has been designed specially for the conditions in which it is to be worked, and the makers state that it can be run on coke or charcoal as well as with anthracite as the fuel. The steam supply necessary for the producer is obtained by evaporation from a shallow pan fitted below the fire-bars. The heat required for this is supplied in part by radiation from the fire, and for the rest by the device of directing the exhaust gases from the engine into an expansion chamber below the water-pan. The provision of this chamber tends to make the steam supply more or less proportional to the load on the engine, and the chamber, moreover, acts as an effective silencer. The supply of water to the scrubber is provided by a pump driven by an eccentric on the engine cam-shaft, which forces the water through the cylinder jacket and thence into the top of the scrubber. The water finally escapes over a wire-mesh cooler, and the total supply required for a day's run is stated to be very small.

MISCELLANEOUS.

Messrs. W. T. Avery, Limited, of Birmingham, had a most varied collection of weighing machinery. Amongst other exhibits at this stand may be noted an attachment for cattle-scales. In practice, excreta from the animals are certain to collect under the platform, and since a link necessarily passes from this space up into the weighing-cabin, the latter is often invaded by most objectionable effluvia. To prevent this Messrs. Avery fit to this link a bell, the outer edge of which dips into an annular water-trough, which thus completely seals off, from the interior of the cabin, the space below the weighing-platform.

Several patterns of automatic weighing-machines for accurately weighing grain, coal, and fluids were also exhibited. The machine for weighing oil is particularly interesting. The hopper, which forms the scale-pan, when nearly full tilts a little, and

GAS-ENGINE AT THE NORWICH SHOW.

CONSTRUCTED BY MESSRS. DAVEY, PAXMAN, AND CO., LIMITED, ENGINEERS, COLCHESTER.

Fig. 18

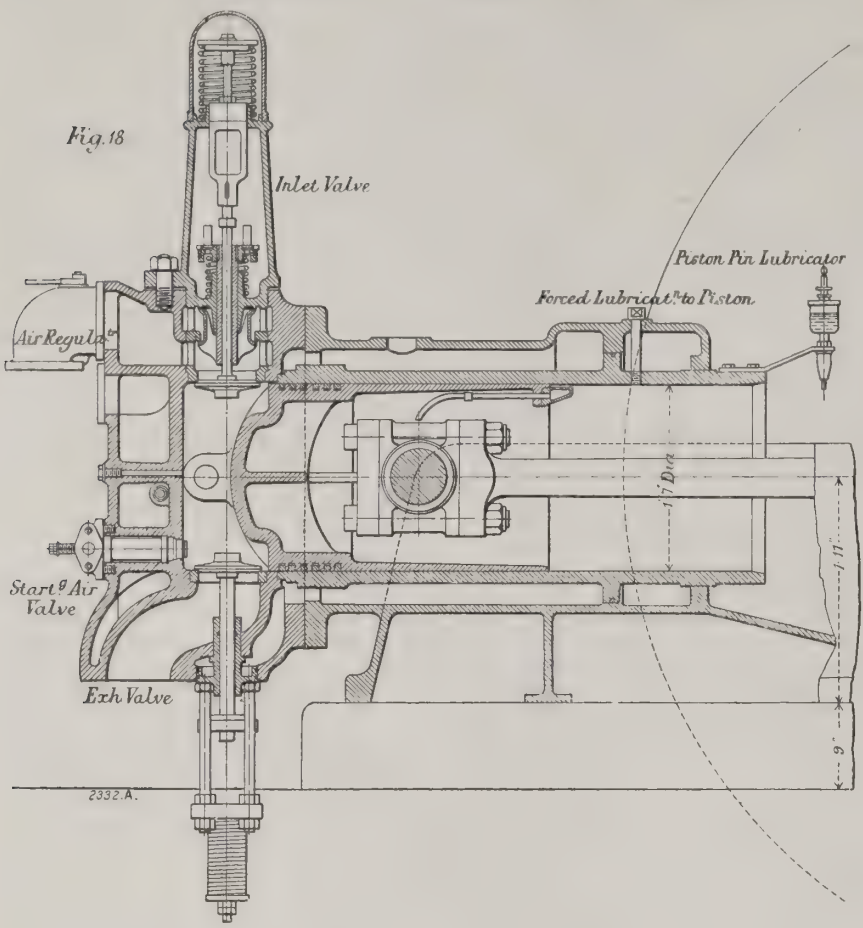

Fig. 19.

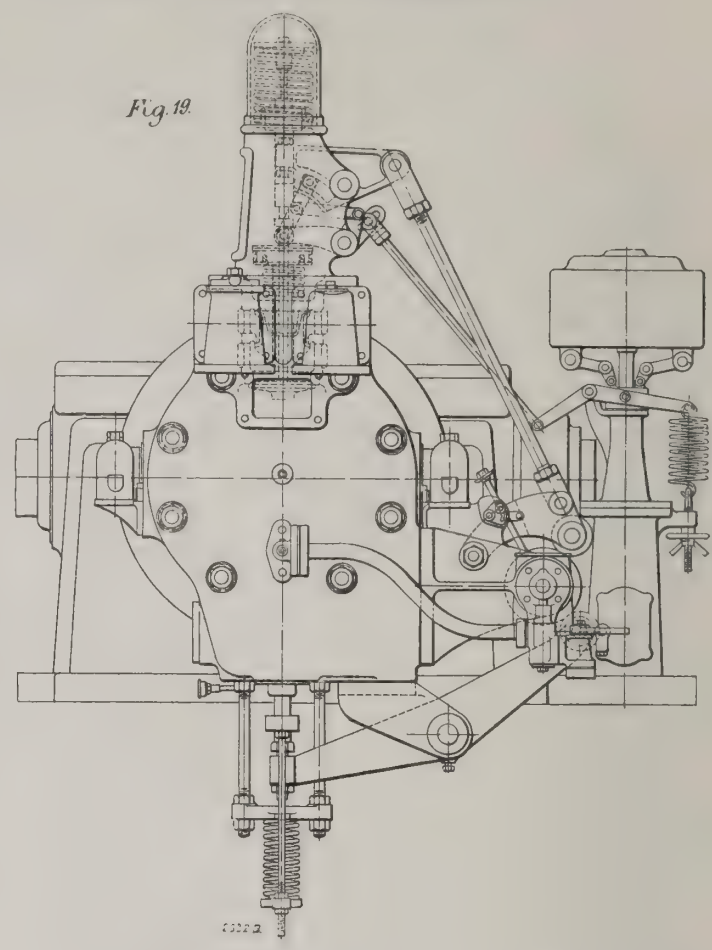


in so doing actuates link-work, which reduces the flow of oil to a dribble. When the exact weight has been run in, the hopper falls, and in the act causes a catcher to come in under the oil-spout. In this catcher any residual leakage is caught ready to be discharged into the hopper when it returns for a new charge. In falling the hopper also tilts, and empties the oil out of its forward end. This is shaped so that the liquid collects there and thus keeps the hopper tilted till it is emptied, save for a mere drain. The hopper is then automatically restored into position for filling, but the drain left in its forward end cannot get back into the bottom of the hopper, but is caught by a diaphragm and directed through a port into the general receiver. Hence, the final drain left, when the hopper is restored into the filling position, has all the time occupied in filling to escape in.

The principal exhibit at the stand occupied by Messrs. Holden and Brooke, Limited, West Gorton, Manchester, was a high-lift centrifugal pump, direct driven by a petrol-engine running at 1200 revolutions per minute. The pump shown has three impellers in series, and delivers 100 gallons per minute against a head of 100 ft. The only stuffing-box is at the suction end of the pump, and this is water-sealed. At the delivery end the shaft does not pass through the casing, but there is an internal bearing, and thus no stuffing-box is required here. This internal bearing is completely immersed in the water under pressure, by means of which the end thrust on the series of impellers is balanced. The whole shaft is allowed a slight end-play. If the pressure in the balance-chamber is too low, the shaft moves so as to increase the head there, and *vice versâ*. There is always a slight leakage through a drain from this balance-chamber, and any lubricant which escapes from the internal bearing is carried off through this drain, and does not mix with the water discharged through the delivery branch. Another exhibit at this stand consisted of a series of hand-wheels for cocks, valves, and the like. In these the rim is constructed as a helix of steel wire, and thus never gets hot, no matter what may be the temperature of the spindle on which the hand-wheel is mounted.

A remarkable series of castings of various kinds was shown at the stand of Messrs. Willans and Robinson, Limited, of Rugby. The firm supply complicated petrol-motor castings to many leading builders, but, perhaps, some of the apparently simpler forms exhibited are really of more interest. Thus they show some remarkable specimens of white-metal bushes, which can be put into place without further treatment. Also they produce cast yellow-brass rods, having properties analogous to drawn or rolled metal; and, further, they show some remarkable examples of solid cast-iron bars, which, though very dense and quite free from blow-holes, are yet soft and readily machined. Unfortunately, the methods adopted in producing these castings are specialities of the firm, so we can merely note the results here without elucidating them.

Undoubtedly, the exhibit made by the Associated Portland Cement Manufacturers, Limited, of Portland House, Lloyd's-avenue, E.C., was one of the most interesting in the Show. At this stand were to be seen fence-posts of reinforced concrete, which, whilst cheaper than oak posts, are much longer lived. Such posts are made in single moulds, the work being quite within the capacity of ordinary farm labour. Generally, sand and gravel are obtainable locally, so that freight has to be paid only on the cement. Water-tanks, likewise made of reinforced concrete, were also on view. These are reinforced with iron rods round the corners and wire netting elsewhere. A 100-gallon tank thus made costs about 11s. for labour and materials. This figure is exclusive of the mould, but as the same mould can be used for as many tanks as the farmer cares to instal, the amount to be attributed under this head to each tank is small. The mould in question is made of wood, and is thus light and easily transported. Block-making machines for making blocks for building purposes were also on view. Such blocks are now finding much favour in certain districts. One colliery company alone has erected 600 cottages built out of moulded concrete blocks. The cost of construction is stated to be generally much cheaper than with brick. The labour needed is less, and the blocks being much larger, the number of joints and the amount of mortar required is greatly reduced. The mixture usually used is about 4 to 1, and one machine will easily make per day 400 blocks measuring 16 in. by 9 in. by 9 in. Drain-pipes of cement-concrete were also shown, and were claimed to be substantially cheaper than the common tile pattern, though equally durable.

The most notable feature amongst the mill machinery exhibited by Messrs. Thomas Robinson, Limited, of Rochdale, was a plan-sifter in which, by adopting two cranks instead of one, vibration is entirely eliminated. This has also had the effect of reducing the power consumed by about a quarter. The same firm also exhibited a large range of wood-working machinery, in particular a two-spindle saw-bench for dimension sawing, with which very accurate work can be accomplished.

The Electrical and Ordnance Accessories Company, Limited, of Aston, Birmingham, showed samples of the Timkin roller-bearing, which has already been described and illustrated in our columns (see ENGINEERING, vol. xc., page 696). This is, of course, of American origin, but its manufacture has been greatly improved at the Aston Works. In motor-car service it has proved most reliable, and is, we understand, likely to become the standard type of bearing used on the omnibuses of the General Omnibus Company, who have made a very extended trial of it, with highly satisfactory results. Single bearings capable of taking a load of as much as 6 tons are now supplied.

A great variety of engineering sundries was exhibited at the stand occupied by Messrs. W. H. Wilcox and Co., of Southwark-street, London, S.E. These included Penberthy injectors, semi-rotary pumps, and also the ingenious slide-valve, seat facing-machine which we illustrated when it was first exhibited at the Gloucester Show of the Royal Agricultural Society.

Fastnut, Limited, of 60, Aldermanbury, London, E.C., exhibited, in addition to their well-known washers, a range of spanners, each jaw of which will take three sizes of nut, automatically adjusting itself to the grip required.

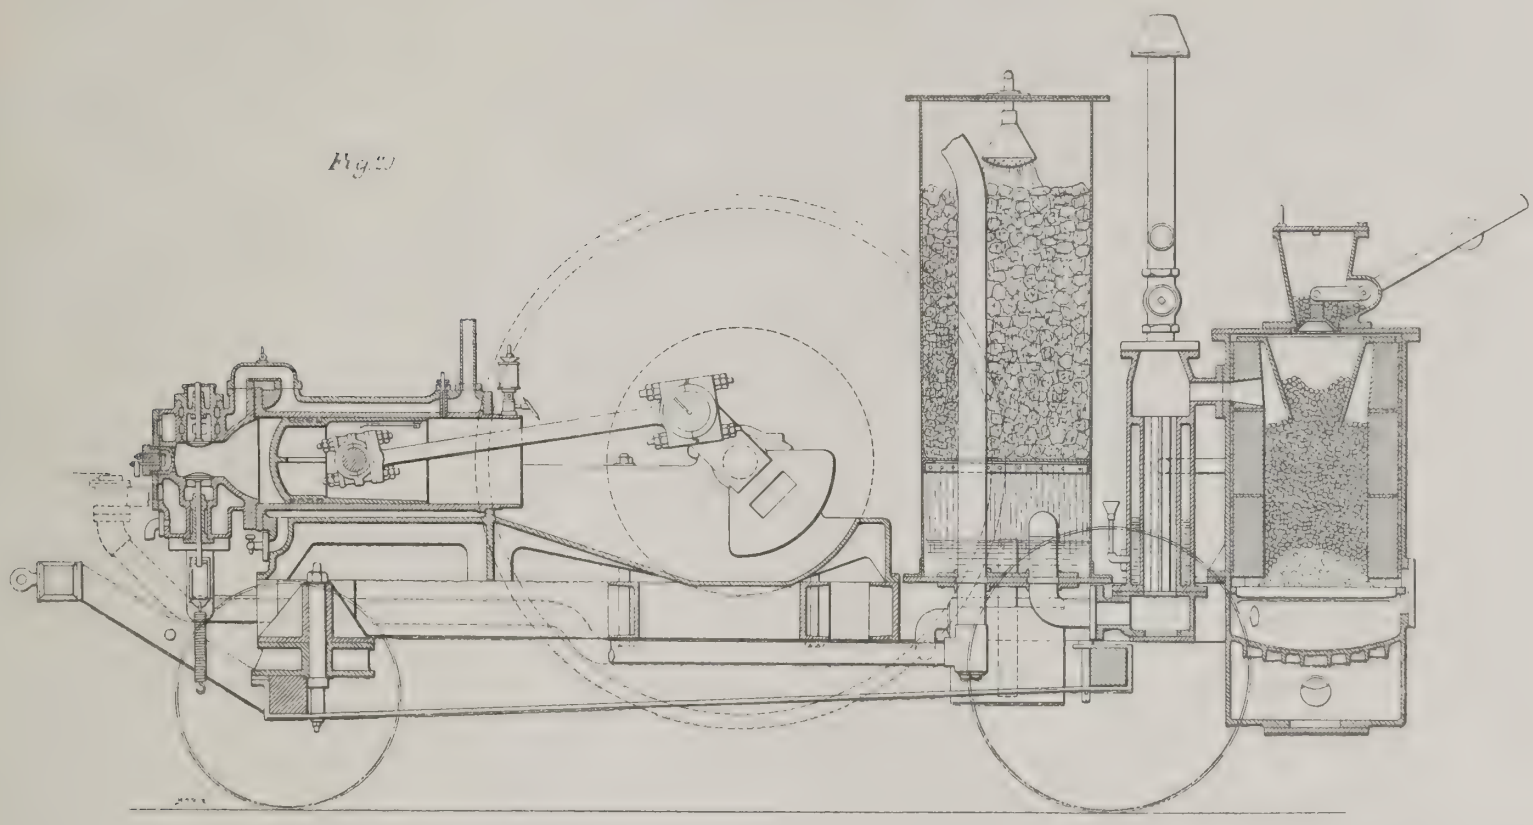
A very interesting exhibit was that of the Palmer Tyre, Limited, who showed in operation one of the ingenious machines used in laying the cords for a Palmer tyre.

The International Harvester Company of Great Britain, Limited, of 80, Finsbury Pavement, E.C., exhibited for the first time at a Royal Show a harvester and binder in which the binder attachment is driven by a small air-cooled petrol-engine.

PORTABLE SUCTION GAS-PRODUCER AND ENGINE.

CONSTRUCTED BY MESSRS. CAPEL AND CO., ENGINEERS, LONDON.

(*For Description, see Page* 5.)



DUNSTON POWER-STATION OF THE NEWCASTLE-ON-TYNE ELECTRIC SUPPLY COMPANY.

In the series of articles dealing with the generation and distribution of electric power on the North-East Coast, which appeared in our previous volume, reference was made to the new generating station which the Newcastle-on-Tyne Electric Supply Company, Limited, were building at Dunston-on-Tyne. No extended description of the station was, however, included in the articles, and we now propose to deal with it in some detail. The station was formally opened on the 5th inst., when a large number of colliery engineers and others visited it.

The construction of the Dunston station was decided upon, about three years ago, in order to enable the power company to cope with the business, which was increasing at the rate of about 20,000 horse-power a year. Although there was still some spare land available at Carville, it was considered better to locate the new installation of generating plant higher up the Tyne. This course was dictated partly with the idea of obtaining plenty of spare land in the neighbourhood of the station, to which it was hoped that new works requiring a large power supply would be attracted as a result of the advantageous terms which could be arranged. The company is already supplying large electro-chemical works near Carville, but the land available for further developments in that neighbourhood is not large, whereas at Dunston the spare land near the station is sufficient to meet the requirements of many years. The new station is built on a site of about 30½ acres, situated on the south bank of the Tyne, about three miles above the High Level Bridge at Newcastle, and some eight miles by river from Carville. The general lay-out of the station follows the unit principle which has long been advocated and practised by the consulting engineers, Messrs. Merz and McLellan, and does not depart in any radical way from other stations built by the same gentlemen. Various modifications and improvements on previous practice suggested by experience have, however, been incorporated into it, and both in virtue of its size, and as an example of the latest practice in power-station construction, the whole installation at Dunston is of much interest.

The general lay-out of the station is well shown in Figs. 1 to 3, on Plate I. It will be seen that it is divided into three main parts, consisting of a coal-store, a boiler-house, and an engine-room. The existing and prospective plant is shown in these figures, but rather than deal with this for the moment it will be well to treat each part of the station in detail, beginning from the coal-store. The noticeable thing about the main buildings, as about those at Carville, is the absence of brickwork and masonry. The whole erection is a steel-framed structure, containing generating plant, and not an architectural building, in which the plant is afterwards placed. The buildings are, in fact, entirely self-supporting, independently of any brickwork, and they are arranged so as to be extended at the minimum possible expense, the walls consisting in the main of corrugated iron and glass. This is well shown in Fig. 5, on Plate II., which is a view of the interior of the engine-room.

Coal-Store.—The coal-store comprises a corrugated iron roof supported on steel girders rising to a total height of 92 ft. from the ground. It is ultimately intended to have additional floors in this store, should it be necessary to increase the capacity, the subdivision of the coal with floors being advisable for ventilating purposes. The coal enters in trucks by railway sidings, shown at the right-hand side of Fig. 2, from which it is discharged into the coal-filler pit. Ultimately it may reach the power-station by river. The coal-conveyor runs from end to end of the coal-store and boiler-house, and is so arranged that the coal can either (*a*) be lifted out of the trucks and deposited in the store, or (*b*) be taken from the trucks and deposited in the coal-bunkers above the boilers, or (*c*) be lifted out of the store and deposited in the bunkers. The coal-handling plant consists of one coal-receiving hopper, into which trucks dump, one four-roll coal-breaker (to crush coal to pass a 2-in. ring), one jigging-screen and gear, and one gravity bucket-conveyor.

From the hopper over which the coal-siding passes the coal gravitates through a regulating-valve at the bottom on to the jigging-screen, from which the screened coal passes direct through a shoot into the stationary automatic filler, into which also the large pieces, after being broken in the coal-breaker, also pass. As will be seen in Fig. 1, the conveyor drive is placed on top of the coal-bunkers, whence the coal-buckets descend at the engine-room end of the boiler-house and pass through the boiler-house basement. When required the coal can be taken from the store by means of hopper shoots fitted with regulating-valves at the bottom, which feed a portable automatic filler delivering into the conveyor-buckets. The conveyor at the present time can handle 40 tons of coal per hour, and is capable of being speeded up above this rate.

Ash-Handling Plant.—The ash-handling plant is quite distinct from the coal-conveyor, and consists of hand-propelled ash-wagons running on rails laid below the ash-hoppers under the boiler-house floor. The arrangement can be best seen in Fig. 3. The rail-tracks along each side of the boiler basement are connected by a cross-over. At the end of each track there is a vertical hoist suitable for raising and automatically tipping the wagon into an ash-bunker. Each hoist and winch can lift, tip, and lower one half-ton ash-wagon in 15 seconds. The winches are driven by induction motors. The ash-bunker, which is situated between the coal-store and the boiler-house, can hold 100 tons of ashes. The bottom of it has a shoot and regulating-valve for discharging ashes into a railway wagon.

Boiler-House.—It will be seen from the plan, Fig. 2, that there is at present one boiler-house, although the station is designed for three. Each boiler-house will contain eight boilers in two rows of four, each row being sufficient for supplying one turbo-alternator unit. There is one coal-store, boiler-house, and set of coal-handling plant for each set of eight boilers, and one boiler-house to each two turbo-alternator units. There is one main steam-pipe, feed-water pipe, hot-well, feed-pump, and set of ash-conveying plant for each set of four boilers. There is one chimney and fan-motor for each two boilers, and there is one economiser, coal-shoot, and ash-shoot for each boiler. In the engine-room each turbo-alternator unit has a complete set of condensing plant and other auxiliaries normally driven from its own "unit" transformer; there being, however, one circulating-pump pit for each pair of circulating pumps. Unlike the arrangement at Carville, there is one set of common main bus-bars, divisible into two sections.

The boilers are of the Babcock and Wilcox marine type. Each unit of two boilers, stokers, superheaters, economisers, fan and chimney, can evaporate continuously under working conditions 60,000 lb. of water per hour, to steam at 200 lb. per square inch above the atmosphere, and superheated to 572 deg. Fahr. at the turbine stop-valve. With coal of 11,000 B.Th.U., under these conditions, the coal consumption does not exceed 4125 lb. per hour. Each boiler has a heating surface of 6725 sq. ft. and a grate area of 168 sq. ft. When forced each boiler can evaporate 37,500 lb. per hour under the same conditions. Each boiler is provided with a complete set of safety, steam, superheat, blow-off, feed, isolating, and other valves, as well as gauges, &c. The larger valves are Hopkinson's, and the smaller ones Dewrance's manufacture. There is a set of fixed tube-cleaning jets, and special arrangements have been made in the boiler casing for enabling samples of the furnace gases to be obtained at different points, while there is a mercury cup for thermometers, fitted to each superheater.

The boilers are carried on steel girders raised on steel columns independently of any brickwork—*i.e.*, all brickwork is removable without disturbing the boilers. The casing-plates of the boilers and superheaters are lined throughout with firebrick and "cellinsulite" slabs. The chain-grate stokers are fitted with wheels on the side frames, so that they may be run out on rails to facilitate repairs and cleaning.

The stoker driving-gear motors have overload spring clutches. A separate motor and driving gear is provided for each boiler. The general arrangement of the boiler can be seen in Figs 1 and 3, while Fig. 6, on Plate III., is a view inside the boiler-house showing the stokers.

Vertically above each boiler there is a Green's economiser, complete with motor-operated scrapers. Each economiser has 288 pipes, and under normal conditions the temperature of the flue gases is reduced to 300 deg. Fahr. at the base of the chimney, while the feed-water is raised from 80 deg. Fahr. to not less than 212 deg. Fahr. at boiler pressure. The economiser-house is an unusually clean and well-lighted place situated near the top of the boiler-house, 55 ft. above the floor level. The bottom of each economiser soot-chamber is arranged with slopes ending in a sliding door. Under these doors there is a line of rails running the full length of the boiler-house, with a movable soot truck, from which the soot is discharged into a hopper placed at one end of the boiler-house, whence it can be discharged into railway wagons.

Each pair of boilers has a chimney and a Davidson "Sirocco" induced-draught fan with water-jacketed bearings arranged with spherical seatings, wide gun-metal rings and large oil-wells, for continuous running. In this detail, as indeed may be noticed throughout the station, there are signs of special care being taken to permit of continuous running without difficulty. The whole design and arrangement of the boiler-house and its details is particularly symmetrical, and there is a marked absence of dark corners, awkward pipes and difficult passages. There is easy access and good lighting for all parts. One of the fans with its motor is illustrated in Fig. 9, on Plate IV.

Before leaving the boilers the steam-piping arrangement should be noticed. From each of the two rows of boilers the steam main is led down into its own main steam-receiver on the engine-room basement floor, whence rising pipes are taken to the steam-separator, and thence to the turbine stop-valves. Another steam-pipe joins the two main steam-receivers together through a U-bend situated between and beneath the turbines. The arrangement may be followed from Figs. 1 and 2. The steam-pipes are of solid-drawn mild steel, with flanges of forged steel, faced straight across after fixing to the pipe. Pipes of 7 in. in diameter and upwards have riveted flanges with beaded pipes. Smaller pipes have flanges screwed on to the pipes, which are then expanded. In most cases the branches on pipes 6 in. in diameter and over are fitted and riveted to the main pipes, but in some cases cast-steel T-pieces are used. Valves under 2 in. in diameter have gun-metal bodies, while larger ones have cast-steel bodies with phosphor-bronze fittings. Valves 5 in. and upwards have gun-metal by-passes. Joints are made with Dixon's graphite and stamped corrugated-metal rings.

The feed-piping is in the form of a complete ring, divided by means of isolating valves into separate sections for each boiler, so that each economiser can be fed from either of two adjacent sections, while each boiler can be supplied direct from the main when the economiser is isolated. The feed-pipes are solid-drawn steel heavily galvanised, T-pieces and bends being of cast iron. The blow-off pipe is of lap-welded steel, and feeds into a boiler-shell used as a blow-off sump. Exhaust and escape piping is also of lap-welded steel. Drain reservoirs are fixed on each side of the boiler-house, beneath the pump-room, in which all high-pressure clean drain water is collected and pumped back to the hot-well.

The water services provided for are five in number: (*a*) Fresh-water service from the town main to the tanks and distribution mains, and from tanks to hydrants and hot-well. (*b*) Salt-water supply (from river) from circulating water pipes to pumps, from pumps to tanks, from tanks to hydrants in the coal-store, boiler-house and engine-house, to fan-cooling water service and connections in other pipe mains This service also supplies the turbine bearings and oil-coolers. (*c*) The service from the salt-water tanks to the high-pressure pump, and from the pump to boiler-tube cleaning hydrants. (*d*) Air-pump discharge from pump to hot-wells, with branches and shut-off valves, so that it can be connected up to a special weigh-tank. (*e*) Circulating-water piping and valves to connect apparatus between main inlet and discharge-pipes.

There are two cast-iron hot-well tanks, each of 720 cub. ft. capacity; one cast-iron clean drain-tank of 80 cub. ft. capacity, and four cast-iron reserve water-tanks for fresh and salt water. Each hot-well has a Schilde water-meter arranged to meter either the whole quantity of the water passing through the feed-pumps or only the amount delivered direct from the air-pumps.

The lagging in the boiler-house consists of Newall's magnesia non-conducting composition with a canvas cover painted with bitumastic paint, the flanges being treated in the same way. Sheet lead is used as a protection on the boiler-drums.

In addition to the apparatus already mentioned there is a Paterson water-softening plant at the top of the pump-room.

Engine-Room.—Passing from the boiler-house up a few steps into the engine-room, the first things to be noticed are the feed-pumps, placed here out of the dust of the boiler-room, in the full light and on the level with the turbines. Steam feed-pumps have been adopted, there being three (one spare), of Messrs. Clarke, Chapman, and Co.'s make, to each boiler-house, each of which is capable of delivering 200,000 lb. of water per hour when working with and against a boiler-pressure of 210 lb. per square inch. Arrangements are made for reducing the amount of superheat delivered to the pump-cylinders, which have to work without any lubrication, the steam-pistons being very deep and having grooves for water packing. The exhaust steam from the pumps goes into the adjacent hot-wells through an exhaust-steam heater, there being a by-pass to the atmosphere if required.

Turbo-Alternators.—The engine-room at present is large enough to contain four turbo-alternators of 8000 kw. each. Three of these have already been installed. The first two sets were of the A.E.G. manufacture, while a third, of the Parsons type, by Messrs. Brown, Boveri, and Co., and Messrs. Richardsons, Westgarth, and Co., has now been put down. The particulars of this latter set are as follow:—The steady speed of the machine does not vary more than 2¼ per cent. between no load and a load of 5600 kw., this steady speed being attained in 5 seconds. A mechanical safety governor is provided to cut off the steam when the speed rises to 1400 revolutions per minute, and this can be tripped by hand. The alternator is of the rotating field type with steel slip-rings, and approximately gives a wave of the sine curve form. The direct-coupled exciter gives 220 volts, and arrangements are made so that excitation of the exciter field can take place from the direct-current system. The voltage regulation is as follows:—When the alternator is giving 5750 volts the throwing off of a non-inductive load of 553 amperes causes a rise not exceeding 10 per cent., the speed and excitation remaining constant, and in throwing off a load of 628 amperes with a power-factor of 0.9 the rise does not exceed 20 per cent. The exciting circuit is so arranged as to allow the alternator voltage to be raised from 5000 volts at no load to 5750 volts at 7000 kw. with a power-factor of 85 per cent., this being obtained when the windings are hot or cold. When delivering 5600 kw. continuously with a 0.9 power factor, the temperature rise does not exceed 45 deg. Cent. above the atmosphere measured by the thermometer, nor more than 50 deg. Cent. when delivering 6250 kw., and the alternator can deliver without dangerous heating, 6250 kw. continuously, 7000 kw. for one hour, and 9000 kw. for two minutes with a power-factor of 0.9. The condenser of the machine can pass 630,000 gallons of water per hour, and can condense 81,500 lb. of steam, and give a 97 per cent. vacuum and 95 per cent. vacuum when condensing 108,000 lb. of steam per hour, with circulating water at 50 deg. and 85 deg. Fahr. respectively.

Three-throw Edwards air-pumps are employed, and an auxiliary pump for raising the air-pump discharge to the hot-well, driven from the air-pump crank-shaft. The circulating-water pumps, which are placed in a pit, take 165 brake horse-power. All the motors in connection with the condensing plant are of the three-phase squirrel cage semi-enclosed type at 480 volts, and they will keep in step down to 300 volts.

Particulars of the A.E.G. sets are as follow:—The maximum output of each machine is 8000 kw. at 5750 volts and 40 cycles per second, the power-factor being unity. The turbine governors are arranged so that speed can be varied 5 per cent. above or below the normal speed while running. This regulation can be effected by hand, or, as is normally the case, electrically from the control-room. The steady speed of the machines does not vary more than 3 per cent. between no load and economical load, and varies less than 5 per cent. between no load and maximum load. There is a mechanical safety governor which cuts off steam when the speed rises to 1320 revolutions per minute, and which can, if necessary, be operated by hand.

The alternators have rotating fields with steel slip-rings and carbon brushes. The wave form is practically sinusoidal. The stators are in two pieces. The rotor windings are excited from exciters fixed on the shafts of the alternators, without outside bearings. The field winding and exciter are such as to allow the voltage of the alternator to be raised from 5000 volts at no load to 5750 volts at 8750-kilo-volt-amperes, with a power-factor of 85 per cent., hot or cold. The terminals are underneath the machine, and the cables are taken out through iron pipes laid in the foundations in such a way as to prevent any accidental contact with live metal. Arrangements are made for earthing the neutral point of the stator through a resistance. The arrangement of the end windings of the alternators are shown in Figs. 18 to 22, on page 9, while a view of the steam end of one of the sets is given in Fig. 10, on Plate IV.

The ventilation arrangements are important. Air is drawn from outside the building by means of a fan on the rotor-shaft, and sent out again through large galvanised iron ducts. These ducts debouch on the north side of the engine-room. The intakes are provided with a filter constructed of blanket carried by wooden frames When the turbines are running at no load and 5750 volts the drop of voltage in throwing on a non-inductive load of 700 amperes is 18 per cent., the speed and excitation remaining constant. The rise of voltage on throwing off a non-inductive load of 700 volts at the same pressure does not exceed 15 per cent.

Surface-condensers are employed capable of dealing with 450,000 gallons per hour of condensing water. When condensing 80,000 lb. of steam they maintain a steady vacuum of 97 per cent., and a vacuum of 95 per cent. when condensing 120,000 lb. of steam, with condensing water at 50 deg. Fahr., the air-pump discharge being at 85 deg. Fahr. The tube-plates are of rolled brass, secured to the shell by delta-metal collar-studs. The tubes themselves are of 99.5 per cent. copper. There is a complete set of valves and gauges, including relief-valve, and vacuum-breaking cock. Three-throw Edwards air-pumps are employed, direct-coupled to three-phase motors, and an auxiliary pump, with electric motor, is used for raising the air-pump discharge to the hot-well.

The circulating-pumps involved some special arrangements. The pumps themselves are situate below the level of the river in pits, 20 ft. 6 in. in diameter and 30 ft. deep, in the engine-room floor, there being one to each pair of pumps and turbines. The pumps are operated through vertical shafts by means of three-phase motors of 80 horse-power, situated on the engine-room floor. A small charging-pump is provided, also operated by a vertical shaft from a motor at the engine-room level, in each pit. The circulating water-pump motor has its weight taken by thrust collars of brass in the upper bearing.

Switch Gear.—The switch-gear arrangements at Dunston are, perhaps, the most interesting part of the station, showing as they do a considerable modification on previous practice. Instead of the usual elaborate switchboard, which forms a striking feature of most power-house engine-rooms, as at Carville, for example, the Dunston engine-room contains practically no high-tension switch-gear or electrical instruments at all. With the exception of certain high-tension panels of "Ironclad" type controlling the unit transformers which supply the auxiliaries belonging to each generating unit, and an indicating wall-ammeter for each generator, the high-tension gear and instruments are installed in a separate switch-house 150 yards away from the engine-room, where are placed both the main switches themselves and the operator and board controlling them. There is, however, in the engine-room near each generator a set of emergency gear for tripping the main high-tension generator switches, with which is interlocked a field switch. Apart from these and the direct-current gear for motor-generators, there are practically no electrical connections or cables visible at all in the engine-room.

The switch-gear may be conveniently separated under the following heads:—

The Control-Boards—in the control-room, for operating the high-tension switch-gear in the switch-house and engine-room.

Main High-Tension Switch-Gear—in the switch-house, controlling the generators, feeders, main bus-bars, and the station power and lighting transformers.

High-Tension Switch-Gear—in the engine-room, for controlling the "unit" transformers in the engine-room.

Low-Tension Gear—three-phase gear in the engine-room, controlling the auxiliaries, and direct-current switch-gear for exciting, lighting, battery-charging and locomotive-driving.

The Switch-House.—The switch-house is a building with concrete roof, 135 ft. long by 33 ft. broad by 32 ft. high. It has two floors, and is divided into two divisions. The front of the building contains, on the ground floor, the offices, lavatories, &c., for the control-room engineers. The control-room itself, containing the operating boards, is on the first floor of the building. The back part of the building, shut off by iron doors, is devoted to the switch-gear itself, the main oil-break switches and bus-bars being on the upper floor, the isolating switches, potential transformers, &c., being in brickwork cells on the lower floor. The bare high-tension connections between main switches, bus-bars, &c., are on the underside of the roof of the lower room, in full view and accessible from the lower room, with ladders, but out of reach of accidental contact.

The Control-Room.—The control-room is a well-lighted department, 40 ft. by 30 ft., with part glass roof. It is mainly occupied by the semi-circular operating switchboard for the feeders, and the smaller board for the generators. With a view to simplicity and facility for extensions, the various operating panels are arranged so that it may be possible at any time to change the particular feeder controlled by any individual operating panel. The control-gear is operated by means of direct current, at a pressure of 100 volts,

DETAILS OF GENERATING PLANT.

Turbines.

Makers	A.E.G	Richardsons, Westgarth, and Co.
Number of machines by each maker	2	1
Type	A.E.G.	2-cylinder Parsons
Type of blading	Impulse	Reaction
Arrrangement of steam passage	Single flow	H. - P. cylinder single flow, L.-P. cylinder part single-flow, part double flow
Specified steam pressure	190 lb. per sq. in.	190 lb. per sq. in.
,, superheat (normal)	190 deg. Fahr.	190 deg. Fahr.

Condensing Plant.

Makers of condensers ..	A.E.G.	Richardsons, Westgarth, and Co.
Number of condensers ..	2	1
Surface of each condenser	17,760 sq. ft.	13,000 sq. ft.
Number of tubes ,,	4162	4720
Arrangement of water passage	Go and return	"Contraflo"
Number and type of air-pumps	Three 3 - throw A.E.G. compound pumps	One 3- throw Edwards with Parsons augmentor
Speed of air-pump ..	200 r.p.m.	150 r.p.m.
Method of drive of pump	60-H.-P. motor	60 H.-P. motor
Number and make of circulating pumps	2 Sulzer	1 Greenwood and Batley
Speed of circulating pumps	390 r.p.m.	600 r.p.m.
Normal power required..	73 b.h.-p.	165 b.h.-p.

Alternators.

Makers	A E.G.	Brown, Boveri, and Co.
Continuous safe output	8000 K.V.A.	7000 K.V.A.
Maximum output for 1 hour	10,000 ,,	7800 ,,
Corresponding power-factor (at continuous and maximum load) ..	0.9	0.9
Voltage	5750	5750

from two small batteries specially used for this purpose. An interior view of the control-room is given in Fig. 11, on Plate IV., while a diagram of the connections of the station is given in Fig. 4, on Plate I.

Each generator-panel has a main ammeter and voltmeter, power-factor indicator, indicating watt-meter, field-ammeter, integrating watt-meter, &c. It has also a switch for controlling the governor of the turbine, and a rheostat hand-wheel in front, as well as a telegraph to each generator. At the end of the generator-board is a synchronising panel with rotary synchronoscope. Each feeder-panel on the feeder-control board has a separate set of instruments and a set of synchronising and volt-meter plugs for synchronising any other generating station with the machines at Dunston. The feeders are protected by Merz-Price balanced protective gear. Both the feeder and generator-panels have chop-over control-switches arranged to make or break the main oil-break switch immediately contact is made. The position of the main oil-break switch is indicated by the lighting of a red or blue lamp, and the last motion performed is automatically indicated by the position of a small coloured pin on the switch-handle.

Switch-Room. — The switch-room itself has two storeys. Access is obtained to the upper storey through an iron door leading from the control-room, and to the lower storey from the passage-way under the control-room. The bus-bars and main oil-break switches are in the upper storey, the connections and isolating switches and current and potential transformers being in the lower storey. The cables from separate generators or feeders are brought up through the ground in separate brickwork cells opening on to the central passage-way in the lower chamber, and closed by expanded metal doors. From three-way dividing-boxes three single connections pass through the wall to brickwork cells on the other side, which are accessible from the outer passages running the length of the lower chamber. Each of the cells contains three single-pole main isolating switches as well as isolating switches for the potential transformers which are placed on the ground below in a small brick cell, protected by sheet-iron doors. From the main isolating switches the three connections are taken up through current-transformers to the bottom connection of the main oil break-switch in the ceiling, the switch itself being placed in the upper storey.

In the upper room three moulded stone tables run parallel to each other along the room, being continuous except for a division of some 6 ft. or 7 ft. in the middle. The main 6000-volt bus-bars rest upon insulators on the central table, which is 5 ft. high, and are protected by expanded metal screens running up to the ceiling for the whole length, thus forming a cage, in which the bus-bars are placed. The bus-bars are divided in the middle of the room by means of a main oil-break switch, capable of carrying 20,000 kw. continuously, and opening under any load likely to be met with. On the two side-tables are fixed the oil-break switches, the left side of the room being entirely devoted to feeders. As stated above, the three connections from the oil-break switch to the bus-bars are carried along the ceiling of the chamber below, and are brought up through three separate bus-bar isolating switches underneath the bus-bar table to the lower side of the bus-bar holding-down bolts. The general arrangement of the gear, as described above, is well shown in Fig. 13, on Plate V.

The main oil-break switches are of the British Thomson-Houston Company's type. Each of the three cylinders containing the actual switch is in a separate cell, and in front of each cell is a "uacolite" door to allow the escape of hot air, &c. The motors operating the switches are arranged to wind up a spring immediately the switch has operated, so that the make or break is instantaneous on the closing of the control switch on the control board. Each oil-brake switch can be made dead by means of isolating switches, there being one set for isolating it from the bus-bars, and one for isolating it from the incoming cables. The bus-bar isolating switches are situate under the bus-bar table, in the ceiling of the lower chamber; but the handles operating them are in the upper chamber on the side of the bus-bar table, each one being exactly opposite its own main switch. As stated, the isolating switches for cutting off the main switch from the tables are situate in the lower chamber. All the high-tension panels are provided with balanced protective gear. There is an air-compressor and set of compressor piping throughout the switch-house for cleaning purposes. A view of one of the main switches is given in Fig. 8, on Plate III., while a general view of the main switch-room is given in Fig. 12, on Plate IV. Various details of the switches are given in Figs. 14 to 17, on Plate V. Fig 7, on Plate III., shows the arrangement of the series transformer and isolating switches.

In addition to the switch-gear already described, there is in the engine-room a neutral isolating switch for each generator and a set of emergency tripping-gear. On the wall of the engine-room opposite each generator there is an indicating ammeter, and each generator also has its own "unit" transforming set in the transformer annexe. The leads for these transformers do not pass through the switch-house, but are taken directly from the generator terminals through "Ironclad" switch-gear of the Reyrolle type, which is placed in chambers on the northern side of the engine-room. The direct-current switch-gear principally consists of a 500-volt traction-board and a 100-volt power and lighting-board, as well as the main lighting distribution fuse-board. The main direct-current switchboard with the motor generators is situate in the corner of the engine-room.

The tables on page 12 give the principal particulars of plant installed.

BOILER EQUIPMENT.

Contractors: Babcock and Wilcox.

Boilers:

Number of boilers installed	8
Type of boilers	Water-tube
Heating surface of boiler	6725 sq. ft.
,, superheater	1156 ,,
Grate area (per boiler)	168 ,,
Heating surface of economiser (per boiler)	2880 ,,
Normal working steam pressure	200 lb. per sq. in.
Normal evaporation per hour per boiler	30,000 lb.
Maximum evaporation per hour per boiler	37,500 ,,

Auxiliary Steam Plant:

Number of feed-pumps	3
Type of feed-pumps	Clarke, Chapman
Maximum capacity per hour, each	200,000 lb.
Disposal of feed-pump exhaust steam	Into hot-well tank

MAIN GENERATING UNITS (FURTHER DETAILS GIVEN ON PLATE I.).

Contractors	A.E.G.	Brown, Boveri, and Co.
Number of sets by each contractor	2	1
Output of each set (at maximum economy)	6500 kw.	6250 kw.
Output of each set (overload)	9000 ,,	7000 ,,
Speed	1200 r.p.m.	1200 r.p.m.

SWITCH-GEAR.

Main High-Tension Gear:

Contractors	The British Thomson-Houston Co., Ltd.
Bus-bars	3 (each of 2½ sq. in. section)
Voltage	5750
Generator panels	1200 amperes capacity
Feeder panels	500 amperes capacity
Step-up transformer panels	1200 amperes capacity
Bus-bar section panels	2000 amperes capacity
Power and lighting transformer panel	500 amperes capacity

Traction Rotary Converter:

Maker	The British Westinghouse Electric and Manufacturing Company, Ltd.
Output (full load)	200 kw.
Overload	25 p.c. for 2 hours
Speed at a frequency of 40 cycles per second	800 r.p.m.

Combined efficiency guaranteed:

At full load	91.0 per cent.
Three-quarters load	89.9 ,,
Half load	87.5 ,,
One-fourth load	81.2 ,,
Terminal voltage	500 to 550 d.c.

Lighting Motor Generators (Two):

Output (full load)	50 kw.
Speed at a frequency of 40 cycles per second	775 r.p.m.

Efficiency guaranteed:

At full load	78.5 per cent.
Three-quarters load	78.0 ,,
Half load	74.25 ,,
One-fourth load	62.0 ,,

Control Battery Charging Motor Generator:

Output (full load)	9 kw.
Speed at a frequency of 40 cycles per second	780 r.p.m.

Secondary Batteries:

Lighting battery:

Efficiency guaranteed when discharged at the one-hour rate	72 per cent. in watt-hours.
One-hour rate of discharge	1000 amperes at 100 volts.

Control Batteries (Two):

Efficiency guaranteed when discharged at the one-hour rate	72 per cent. in watt-hours.
One-hour rate of discharge	100 amperes at 100 volts.

WOLSELEY PETROL-ENGINES FOR MOTOR LIFEBOATS.

ON pages 10 and 11 we reproduce perspective views and drawings of a four-cylinder engine of 34 horse-power when running at 700 revolutions per minute, specially designed and constructed by the Wolseley Tool and Motor-Car Company, Limited, at their Adderley Park Works, Birmingham, for motor lifeboats, to be stationed one at St. Abbs and the other at Seaham Harbour. Each cylinder, of 5 in. bore by 6½ in. stroke, is cast singly, with heads and jackets in one piece, and mounted on a cast-iron crank-chamber, and are made interchangeable.

The walls are $\frac{7}{16}$ in. thick, and the water-jackets are $\frac{5}{16}$ in., made of close-grained cast iron. The cylinder liners are capable of withstanding an hydraulic pressure of 700 lb. per square inch, and the jackets of 50 lb. per square inch. The jackets are fitted with large covers at the sides, to ensure accurate coring, and to be used, when necessary, as manholes for cleaning purposes. The exhaust-valves are arranged on the port side, and the induction-valves on the starboard side. The crank-case is of cast iron, having six arms for bolting to the engine-bearers.

The crank-shaft is made of Vickers' nickel-chrome steel, and is carried in five bearings. The crank-shaft journals are 2⅝ in. in diameter, and the crank-pins 2½ in. in diameter. The total area of any pair of these journals is equal to 81 per cent. of the piston area, and the crank-pins to 37 per cent. The crank-shaft is so arranged that the bottom cover of the crank-chamber may be removed for inspection purposes without affecting the alignment of the shaft. The connecting-rods are made of high-grade steel and bushed with phosphor-bronze for the gudgeon-pins; the big ends are of phosphor-bronze, white-metalled. The pistons are of close-grained cast iron. Four piston-rings are fitted, the position of these rings being fixed by means of pegs fitted into the pistons. The main bearings are of phosphor-bronze, white-metalled.

The cam-shafts, as shown in Figs. 2, 3, 6, and 7, are arranged on each side of the engine, and are driven from the crank-shaft by enclosed metal gears. The starboard cam-shaft has ignition cams embodied for driving the low-tension ignition mechanism, and the port cam-shaft has an eccentric embodied for driving the air-pressure pumps.

The valve-operating plungers are adjustable, and fitted with hardened-steel rollers to work in phosphor-bronze plunger guides. Half-compression of the sliding type is fitted on the port side of the engine, and works in connection with the exhaust-cams. The ignition is of the "Bosch" low-tension magneto type, the make-and-break mechanism being operated by means of cams on the starboard cam-shaft; the tappets and rods are adjustable. The magneto has a fixed point of firing. In addition to the low-tension, provision is made for high-tension sparking-plugs. The carburettor is of the float-feed and spray type, so arranged that it is capable of running the engine satisfactorily when it is placed at a permanent longitudinal angle of one in four on a slipway, and at a momentary list to either port or starboard of 45 deg., and at a permanent list to either port or starboard of 25 deg. An annular float is fitted. An auxiliary jet is embodied to facilitate starting. The fuel supply to the carburettor is maintained by means of an air-pump of the plunger type, driven off the cam-shaft by means of an eccentric.

The engine is fitted with a centrifugal governor, so arranged as to act on a compensated throttle, independent of the hand control, and capable of controlling instantaneous variation from full load to light load within 12 per cent., and a steady variation of full load to light load of 6 per cent.

The water-cooled exhaust branch, fitted on the port side, is made of heavy-gauge oxy-acetylene welded steel, to exhaust aft, and so arranged that it will couple up to a water-cooled silencer.

A fly-wheel, of cast iron, of 16 in. in diameter, is fitted. All main bearings are lubricated by means of a pump, which positively forces oil to all important bearings, and feeds the centrifugal oilers which lubricate the big ends of the connecting-rods, The oil is pumped from a separate 2½-gallon tank to the bearings and centrifugal oilers. The oil which drains into the base is pumped therefrom and forced through a large strainer in the oil-tank. A supplementary lubricating system is embodied, whereby the bearings, connecting-rods, and pistons may be lubricated by splash.

THE INSTITUTION OF NAVAL ARCHITECTS.

*President's Address.**

YOUR ROYAL HIGHNESS, MY LORDS, LADIES, AND GENTLEMEN,—When the Council and Members of this Institution did me the honour to select me as their President in the spring of this year, I felt that in accepting that office—which I did with a high sense of its responsibilities—I had a difficult task before me, to follow with equal success in the footsteps of the very distinguished line of predecessors which have, from its inception, occupied the presidential chair. To succeed such men as Lord Hampton, Lord Ravensworth, Lord Brassey, Lord Hopetoun, Lord Glasgow, and Lord Cawdor is in itself an honour upon which I place a high value, and an incentive to me to maintain the high standard of tradition they have set.

Upon the untimely and lamented death which created the vacancy I am now called upon to fill I will not attempt to dwell. Such an occasion as this is not one for sad thoughts. Yet I would say just this, that in losing Lord Cawdor at the very beginning of this memorable year the Institution has shared in a very particular degree the loss which has been felt through a wide range of national enterprises. The call to high political office had come to Lord Cawdor at a time when his great administrative capacity had already been proved in other directions. His forceful personality and the zeal and vigour which he threw into his political work clearly marked him out as a leader whom men would be proud to follow. That the Institution of Naval Architects would have derived immense advantage from his wise and experienced leadership is an opinion which will, I think, be very generally shared.

Now the brilliant gathering which has assembled to-day to celebrate the Jubilee of the Institution of Naval Architects has been convened, as I understand it, for a twofold purpose. The occasion is, primarily, a commemorative one. The founding of this society fifty-one years ago marked an epoch in the history of naval architecture, which synchronised with the first construction of sea-going iron ships, with the introduction of protective armour, and with the advance to a position of great importance of the naval engineering element. I do not propose to pursue the train of thought which the contemplation of these subjects conjures up. They will be dealt with in the papers to be read by those distinguished naval architects, Sir William White and Sir Philip Watts, to whom this country, as well as this Institution, owes a deep debt of gratitude for their long, whole-hearted, and exceptional services to the profession which they so brilliantly adorn. Neither shall I trench on the engineering question, which no doubt will be adequately dealt with in his paper by Engineer Vice-Admiral Sir Henry Oram, whose skill and foresight have contributed largely to the very great importance of his department in the naval organisation of this country.

There existed, as you are aware, a much earlier society for the Improvement of Naval Architecture, founded shortly before the close of the eighteenth century. But its existence was a brief one, and, from the moment of its untimely dissolution until the middle of last century there had been no similar body in existence. The founding of the Institution of Naval Architects gave practical expression to the aspirations of the representatives of that most important science—the science whose principles govern the construction and equipment of ships—to incorporate themselves into a permanent body in order to advance by every legitimate means the wide and varied interests which form a common bond between its members. Among the primary factors that contribute to all progress in these matters are the educational facilities which are open to those desirous of taking up naval architecture or marine engineering as a career; the framing and administration of laws affecting the construction and safety of ships, and the promotion of investigation and research into numberless problems that await solution. These and similar questions have been, and are being, carefully considered, and the difficulties are being overcome by the combined efforts, and the voluntary work freely given, of the leaders of thought and action in this great section of our national industries.

We live in a period of incessant change and movement. One has only to glance back to the time of the last International Congress, held here in London in 1897, to see what remarkable developments have taken place in that brief period. Mr. Goschen, the then First Lord of the Admiralty, in his speech of welcome to the Congress expressed the hope that the outcome of that meeting would not result in discoveries which would make obsolete our fleet as it then existed. Since then fourteen years have elapsed, and what has happened? Displacement and speed have gone up by leaps and bounds, gun-power for attack and armour for defence have increased in efficiency with almost equal rapidity. Concentration of power has led to the creation of warships undreamt of in 1897. Improvements in propelling and auxiliary engines, and the introduction of new forms of fuel and combustion, have brought about equally startling results in speed, power of endurance, and methods of propulsion. Submarines, the dream of that fascinating writer, Jules Verne, are an accomplished fact; and if their range of action for attack is not yet equal to that of Captain Nemo's famous Nautilus, they are undoubtedly a great potential factor in our organisation for defence.

In the sister art of merchant-ship construction the advances made in recent years have been almost equally great, and the Transactions of this Institution contain remarkable evidence of the progressive spirit that has animated the designers and constructors of ships and their machinery during this period. Well deserved is the recognition that has now been freely accorded to this Society. Its growing membership and financial prosperity are valuable assets, but more valuable even than these is the constant and sympathetic interest of the great administrative departments of the State. The presence of their distinguished representatives to-day is a strong and welcome proof of this friendly attitude. But, above all, we value the gracious action of our Sovereign in extending his patronage to this Institution. By the granting of a Charter of Incorporation, His Majesty has undoubtedly established it upon a new and permanent foundation. Moreover, it was King George's intention, had circumstances permitted it, to have presided last year over the opening ceremony of these Jubilee Meetings. Had not the hand of death descended so untimely upon our bereaved nation little more than a twelvemonth ago, that intention would have been realised. As it is, we are fortunate in having had our invitation so graciously responded to this year by H.R.H. the Duke of Connaught. In accepting the Honorary Presidency of this Congress, and in consenting to open its proceedings, His Royal Highness has shown once again that mark of Royal interest in the intellectual activities of this realm which has signalised above all others the reigns of our august Sovereigns, King George V., King Edward VII. and Queen Victoria.

I alluded just now to the object of this gathering being twofold: the second aspect of its bearing upon our work is, in my judgment, no less important than the first. The International Congress in Naval Architecture and Marine Engineering, which forms the principal feature—if not the actual *raison d'être* of our Jubilee Meetings—is intended primarily to bring together from all parts of the world the great leaders in this sphere of industrial activity. These are the men whose brains have conceived the mighty structures, the floating fortresses and palaces that now compose our fleets of war and commerce. To

* Delivered by the Most Honourable the Marquis of Bristol at the Jubilee Meeting of the Institution of Naval Architects on July 4.

their energy and skill, to their infinite capacity for taking pains, to their splendid victories of mind over matter, we owe whatever we possess of value to those "that go down to the sea in ships and do business in great waters." That we should be honoured on this occasion by the presence of such distinguished representatives of other nations is a compliment of which we deeply appreciate the value and significance.

To some of these nations we, in our sea-girt islands, feel a debt of gratitude for many of the forward steps that have been taken, and many of the gaps that have been bridged, before ships could be built of the types and size and speed that we see afloat to-day. With others (of these nations) the bond lies in the debt they owe to those of our countrymen who have given freely of their technical skill and knowledge in helping to lay the foundation of the great young navies that are now counted among the leading naval powers of the world.

The Council desire to signalise the present occasion, and to do honour to their guests from abroad. They have accordingly resolved to add to their list of honorary members by inviting the distinguished personages whose names I am about to read, to become honorary members of the Institution—the highest distinction which it is in the power of the Council to confer. Before reading these names I would like to remind you that His Majesty the German Emperor was the first among reigning sovereigns to accept this distinction, and that Rear-Admiral H.I.H. Grand Duke Alexander Michaelovitch is the distinguished representative of the Russian Navy upon our existing list. The newly-elected honorary members are as follow:—H.M. the King of Norway, H.M. the King of Spain, H.M. the King of Sweden, H.I.H. Prince Henry of Prussia, H.I.H. Archduke Ferdinand, H.R.H. the Duke of Connaught, H.R.H. the Duke of Genoa, Prince Roland Bonaparte, Lord Rayleigh, Admiral Dewey, Admiral Togo, and Admiral Ijuin.

Meetings such as this are memorable landmarks in the history of an institution. My own appearance among you dates as it were from but yesterday, but there are many present who will recall the splendid reception which they themselves received during the delightful visits that have been paid to foreign capitals and British seaports—Paris, Berlin, Hamburg, Düsseldorf, Bordeaux, Glasgow, Newcastle, and Sunderland, Liverpool, Cardiff, Southampton, Belfast, Dublin. All these have shown what a welcome can be given to our Naval Architects and Marine Engineers. The present occasion furnishes a welcome opportunity to show our hosts of former days that we are not unmindful of their hospitality. Our Institution stands no longer alone; in all countries where the naval architecture counts, societies have sprung up, and under able leadership are sowing the seeds of knowledge and reaping the harvest of thought and experience. Their members are, in many cases, our members, and the bonds of friendship that have ever subsisted between us will, I earnestly hope, continue to strengthen with age.

Gathered as we are to-day under one roof to celebrate the first fifty-year stage of this journey of ours, I cannot but look forward with confidence to a future that bids fair to keep the science of naval architecture in the forefront of the march of human progress.

In conclusion, I will ask H.R.H. the Duke of Connaught to accept once more our hearty thanks for his great kindness in coming at considerable personal inconvenience, in the midst of the numberless engagements of this ever-memorable Coronation year, to preside over our inaugural meeting, and to allow me in the name of all assembled here to-day to send the following telegram to His Majesty the King, Patron of the Institution of Naval Architects:—

"HIS MAJESTY THE KING, WINDSOR CASTLE.

"Members of the Institution of Naval Architects and their guests, assembled in an International Congress to commemorate the Jubilee of this Institution, tender to your Majesty a dutiful message expressive of the loyalty of your Majesty's subjects, and of the respectful homage of their guests from abroad. Your Majesty's constant devotion to the Naval and Maritime interests of this realm leads us to hope that these meetings may prove worthy of your Majesty's gracious consideration.

"BRISTOL, President."

THE HISTORY OF THE INSTITUTION OF NAVAL ARCHITECTS AND OF SCIENTIFIC EDUCATION IN NAVAL ARCHITECTURE.*

By Sir WILLIAM H. WHITE, K.C.B., F.R.S., LL.D., D.Sc., D.Eng., Hon. Vice-President.

ON this occasion the Council have thought it desirable to have included in the programme of papers an epitome of the history of the Institution. The records of that history lie scattered in fifty volumes of the Transactions. The labour of compilation and condensation would necessarily be great if the task were undertaken by one who had not been personally cognisant of the principal events. Personal knowledge is of the greater importance in connection with the earlier periods of that history, because many of the records are incomplete, and only those who were then taking an active part in the conduct of the Institution can speak with full knowledge. There are few men among us now who were original members of the Institution; amongst these, Sir Nathaniel Barnaby, our respected Honorary Vice-President, would have been best qualified to perform the task had his strength permitted. He is the only survivor of the little group of men whose meeting on January 16, 1860, practically secured the establishment of this Institution. He was an original member, and his contributions to the Transactions commenced with the first volume. He became a Member of Council forty-six years ago, and has never failed to do his best in the service of the Institution. Unfortunately, Sir Nathaniel Barnaby did not feel equal to the task; the Council therefore requested me to undertake it. Owing, as I do, a deep debt of gratitude to the Institution—because action taken by its Council in 1863 led to the establishment of the Royal School of Naval Architecture and Marine Engineering, in which my professional education was received—there could be only one answer to that request. Sir Nathaniel Barnaby has been kind enough to supply information respecting certain incidents of the first five years, of which I had no personal knowledge. Even with that aid, the preparation of this paper has not proved an easy matter, although from 1866 onwards it is possible for me to speak of "what I have seen and heard."

In that year, as a student of the Royal School, I first attended the annual meetings of the Institution. Since that time I have been privileged to take part in most of the meetings held both at home and abroad. My membership dates from 1868, service on the Council from 1877, and for twenty-five years my name has stood on the list of Vice-Presidents. Failing Sir Nathaniel Barnaby—whose position is unique—there are few men left on our list who have had a longer acquaintance with the working of the Institution, or who have been more intimately concerned with its administration and development, and in telling the story my endeavour has been to state the facts simply and clearly, and without bias. If there has been any unconscious bias, it may be attributed to the strong personal attachment which I feel towards the Institution, and to a profound conviction that, having accomplished a great work in the past, the Institution will do an even greater work in the future by promoting knowledge of both the science and practice of shipbuilding and marine engineering, and by continuing to be the place of assembly most favoured by the naval architects and marine engineers of the world.

THE CONDITION OF NAVAL ARCHITECTURE IN 1860.

When the founders of the Institution met in January, 1860, to start the enterprise of which we are celebrating the Jubilee, conditions of an altogether unprecedented character prevailed. It was a period of transition, indeed almost of revolution, in regard to the design, construction, and propulsion of ships. The steam reconstruction of the Royal Navy was in full progress, after long hesitation and much opposition from advocates of sail-power. Armour had not long before been introduced as a protection for warships against horizontal shell-fire. The first French sea-going ironclads had been completed recently, and were undergoing trials. Great differences of opinion still continued as to the proper choice between following the French lead, or perpetuating the construction of wood-hulled line-of-battleships. After heated debate the first four British sea-going ironclads had been ordered in 1859, and these vessels were building when the Institution was founded. Almost simultaneously orders had been given to build a considerable number of unarmoured line-of-battleships and frigates, and to convert sailing-ships into screw-steamers. Amongst my earliest employment (as an apprentice to the master shipwright at Devonport) was work on one of the vessels, some of which were never completed.

The use of iron as the principal material for shipbuilding was in process of extension, yet wood still maintained its pride of place, especially for warships. Prior to the use of armour attempts had been made to build unarmoured frigates with iron hulls, and as the result of firing trials against targets representing the sides of those vessels it had been decided to employ them in transport service, and to revert to wood, as better fitted to withstand attacks from the naval ordnance of that time. Smooth-bore guns and spherical projectiles were still in common use, although Armstrong, before this date, had commenced to manufacture breech-loading rifled ordnance. Gun-mountings were of the most primitive character, and were practically unchanged from the preceding century; manual power was depended upon for working guns. The heaviest guns carried by British men-of-war were 68 pounders, weighing 95 cwt. Even in the latest types of warships then extant engine power was regarded as only auxiliary to sail power. That principle was adopted also in the designs of our first ironclads (the Warrior and her consorts), all of which were capable of proceeding and manœuvring under sail alone. Iron and steam were steadily making way, but conservative opinions were still widely held. The advocates of radical change were met with strenuous opposition, and this was natural enough, seeing that for centuries changes in shipbuilding and armaments had been few and small.

The introduction of armour protection in warships overcame objections to the use of iron for warship building which had been previously regarded as conclusive. In the mercantile marine the use of iron hulls had become more general, but in 1860 two-thirds of the mercantile tonnage built in Great Britain was in wood. Brunel and others had shown what could be done with the material. Striking illustrations of its merits and possibilities had been given in the Great Britain (1843) and in the Great Eastern, which had started on her first cruise in September, 1859, and was still on trial when the founders of this Institution met in January, 1860. Even now, nearly sixty years after the preliminary designs for the Great Eastern were put in hand by Brunel, one wonders at the boldness of the conception and the degree of success attained. That wonder grows when the Great Eastern is compared with the largest contemporary steamships of 1860. The finest Cunarder was 360 ft. long, 3300 tons (gross); the largest steamer in the Peninsula and Oriental service was a little more than 300 ft. in length and 2000 tons (gross); the Royal Mail Company had as their finest vessels steamers of about the same size as the Cunarders; the mail steamers on the Cape service were 180 ft. in length and 550 tons (gross); in the Royal Navy the largest wood-built line-of-battle ships were 260 ft. long, of 7000 tons displacement, and about 4000 horse-power. The Orlando class of frigates were 300 ft. long, of 5600 tons, and with engines as powerful as the line-of-battle ships; but they remained but a short time on service, as their structural strength proved insufficient for such powerful engines. The Great Eastern was 680 ft. in length, of nearly 19,000 tons (gross), and about 30,000 tons displacement, her engines developed a total of 10,000 horse-power; five or six times as powerful as the engines in the largest and fastest mail steamers of the period, and two-and-a-half times the power of the largest warships. Brunel made a gigantic experiment which proved a success on the technical side, although it resulted in a commercial failure. Scott Russell, one of the principals amongst the founders of the Institution, had been associated with Brunel and had undertaken the contract for the ship and her paddle-engines. For nearly half a century she remained unsurpassed in size, and she will always be regarded as having been a monumental structure which should have been preserved.

The theory of naval architecture as it existed in 1860 was sketched by Dr. Woolley in the first volume of the Transactions, and no better authority for dealing with the subject could have been found at that date. In that paper full acknowledgment was made of the valuable work done in the eighteenth century by French writers, and under the auspices of the Academy of Sciences. By these pioneer workers a mathematical theory of naval architecture had been initiated, and fundamental principles formulated. Dr. Woolley also indicated briefly the contributions which had been made subsequently by British writers, and suggested directions in which further investigations might be made with advantage. He illustrated and emphasised the inexact and incomplete state of scientific knowledge, but contended that it was essential for "naval architects to drink deeply of the well of scientific truth, and to be imbued largely with the spirit of philosophical inquiry." At that time, however, only a small proportion of British shipbuilders made any pretence to scientific knowledge or method; most were content to follow precedent and experience. In face of the radical changes consequent upon the introduction of steam power, iron hulls, and armour protection, as well as consequent developments of naval ordnance, time-honoured procedure in the designing of ships necessarily had to be abandoned. "Rules of thumb" based upon experience, and not upon fundamental principles, had to give place to scientific method; the trained naval architect began to come to his own. Practical experience still continued, and ever will remain, an essential part of successful engineering operations; but experience alone could no longer suffice as it had done throughout the long period when types of ships remained practically unchanged. Scientific knowledge and scientific analyses of the results of experience became necessary when entirely new conditions had to be dealt with. Novel types of ships had to be designed, in which dimensions, forms, structure, protection, propulsive apparatus, and armaments all constituted or involved departures from precedent, and new methods became a necessity.

The advantages of scientific method had been recognised long before the ironclad era began; indeed, the proofs of its beneficial influence lay open to those who cared to seek for them, and were summarised by Dr. Woolley. France had shown the way in this direction, and attempts had been made in Great Britain to rival French methods by the establishment of societies for the improvement of naval architecture and the founding of two schools of naval architecture, the first in 1811 and the second about thirty-seven years later. Both schools had been abolished prior to 1860 by politicians who were not capable of appreciating their value, British naval architects had to send their sons abroad for scientific instruction. Fortunately for this country, however, naval architects who had been trained in these schools remained available when the crisis of which a sketch has been given arose fifty years ago. These were the men who took the responsibility of the steam and ironclad reconstruction of the Navy, and also played a prominent part in founding this Institution.

FOUNDATION OF THE INSTITUTION OF NAVAL ARCHITECTS.

The need for such a society, as well as the demand for scientifically-trained naval architects which followed upon the events above described, had much to do with the immediate success which was obtained by this Institution. It was founded at a psychological moment, and all classes interested in shipbuilding welcomed it. Members of both the British Schools of Naval Architecture gave sympathy and active assistance, and they were joined by a little band of private shipbuilders and marine engineers, whose professional training had been received elsewhere, but who shared in the conviction that the time had come when the claims of science, as well as those of practice, must be recognised, if British shipbuilding was to maintain its ancient renown under entirely new conditions.

In the first volume of the Transactions may be found an interesting account written by the then secretary (Sir Edward Reed) of the preliminary steps which were taken by the founders prior to the meeting on January 16, 1860; the proceedings at that meeting and those at a second meeting held a fortnight later are also described. The principal facts may be briefly sumarised. About forty persons had been invited to attend the meeting; many of them were in sympathy with the proposal, but

* Paper read at the Jubilee Meetings of the Institution of Naval Architects, July 4, 1911.

only eighteen were present. Of these, ten were or had been in the shipbuilding department of the Royal Navy, Dr. Woolley, who had been principal of the second School of Naval Architecture, attended, and was accompanied by four of his pupils. Six gentlemen represented private firms of shipbuilders and marine engineers; one was a barrister, keenly interesting in canoeing and yachting, who became better known later on as "Rob Roy" McGregor. The list of men present who had been trained outside the Naval Service was small but representative. It included Scott Russell; John Penn, the eminent marine engineer; John White, of Cowes, member of a historic family of shipbuilders; Grantham, a recognised authority on iron shipbuilding; and the two principal surveyors of Lloyd's Register of Shipping, an organisation which had already done valuable work in assisting the development of the mercantile marine, and has since attained an unrivalled position in connection with the survey and classification of British and foreign shipping. This little company, after hearing the explanatory statement read by the secretary, had the courage to resolve unanimously as follows:—

"We who are present do now constitute ourselves an Institution of Naval Architects for the purpose of advancing the science and the art of naval architecture."

Without delay or adjournment steps were taken to give effect to this resolution. A list of officers of the Institution was considered and approved; Sir Edward Reed was elected permanent secretary; committees were appointed to consider and report on the general constitution and management of the Institution, the qualifications for admission of members and associates, and the names of persons who should be invited to join the Institution at its commencement. A fortnight later a second meeting of the founders and officers was held; the reports of committees were then received and dealt with: and within a month from this second preliminary conference the inaugural meetings of the Institution were held, extending over three days. At these meetings many valuable papers were read and discussed, and the Institution was fairly launched under most promising auspices. Throughout this stage the new Institution received kindly assistance from the Society of Arts, in whose rooms the first meetings were held, as have been all subsequent annual spring meetings. Limited space made it impossible to hold our present gathering in the hall around which so many memories have gathered during the last fifty years; but it is only right on this historic occasion to place on record once more our grateful acknowledgment to the Council of the Society of Arts for their long-continued courtesy and kindness.

Constitution and Organisation of the Institution.

A declaration of the "objects of the Institution" was made at the outset and printed in the first volume of the Transactions. This declaration has never been varied; it still adequately represents our work, notwithstanding the great changes which have occurred during the intervening period, and is now reproduced as an illustration of the wisdom and foresight of our founders.

Objects of the Institution.

"The objects of the Institution of Naval Architects—which was established to promote the improvement of ships, and of all that specially appertains to them—are comprised under three heads:—

"First, the bringing together of those results of experience which so many shipbuilders, marine engineers, naval officers, yachtsmen, and others acquire, independently of each other, in various parts of the country, and which, though almost valueless when unconnected, doubtless tend much to improve our navies when brought together in the printed transactions of an institution.

"Secondly, the carrying out by the collective agency of the Institution of such experimental and other inquiries as may be deemed essential to the promotion of the science and art of shipbuilding, but are of too great magnitude for private persons to undertake individually.

"Thirdly, the examination of new inventions, and the investigation of those professional questions which often arise, and were left undecided before the establishment of this Institution, because no public body to which professional reference could be made, then existed."

The constitution, bye-laws, and regulations of the Institution as originally framed equally illustrate the ability of those who were responsible for their settlement. These laws have been varied or amended in the light of subsequent experience and altered conditions, but the fundamental principles have been maintained. One passage in the statement of the first secretary, Sir Edward Reed, puts the matter clearly and may be quoted:—

"It was felt that the naval architect—to whom alone the ship as a complex whole is a subject of study—was the only proper person to give designation and character to the society, and consequently it was decided. . . . . that its title should be the 'Institution of Naval Architects.' But naval architects alone do not produce ships. With them must be associated—and closely associated, too—the shipbuilder, the man of science, the seaman, the engineer, the mast-maker, the rigger, the sail-maker, the smith, and others, or no ship could ever be built and equipped. Hence it was concluded that for the Institution of Naval Architects to become a vital and vitalising body it must draw into association with itself persons from all such classes. This it is proposed to do by the establishment of a class of associates—a class which it is believed will become very numerous, and will render most invaluable aid to the Institution."

For nearly twenty years after the Institution was started the number of associates exceeded that of professional members of the Institution, thus realising the anticipations of the founders. Since 1879 the conditions have been reversed and the professional side of the Institution has largely outgrown the associate class. While this increase in professional membership is a subject for congratulation, it is a matter for regret that a corresponding increase of associates has not taken place. Everything possible has been done by the Council to encourage that increase. The qualification for associateship has been framed on broad lines, and liberally interpreted; yet the number of associates on the roll of the Institution at the present time is no greater than was the corresponding number in 1862, although in the interval the number of professional members has increased twenty-fold. It is devoutly to be desired that before long there may come a marked change. Associates, according to the regulations, "shall be qualified, either by profession or occupation, or by scientific or other attainments, to discuss with naval architects the qualities of a ship, or the construction, manufacture, or arrangement of some part or parts of a ship or her equipment." Within these wide limits a great number and variety of persons exist who are interested in ships and shipbuilding—men of affairs, politicians, men of science, shipowners, seamen, engineers practising in many branches, manufacturers of materials, machinery and equipment, and many others. All of these can aid in the discussion and settlement of numerous and difficult problems incidental to the design, construction, and propulsion of ships; many of them are possessed of special knowledge and experience which entitle their opinions to great respect. The maintenance of British supremacy in shipping, both in the war fleet and the mercantile marine, is of vital importance, and can only be secured by the co-operation of all classes. It is undoubtedly true that the work done by the Institution of Naval Architects has furthered this great end, and has contributed in no small measure to the commanding position which British shipping now occupies. On public grounds, therefore, apart from the interests of the Institution itself, one may plead for a realisation of the hope expressed fifty years ago that the associate class "will become very numerous." It has already been conclusively demonstrated that this class can "render most invaluable aid to the Institution," and although the roll contains many eminent names, a much greater number of representatives of the class is desired. Associates have from the first had adequate representation on the Council and a large share in the management of the Institution, and all the presidents have been associates.

In this respect the Institution stands alone amongst technical societies, all others having professional presidents. The reason for the procedure which has been adopted was stated as follows in 1860:—"In view of the national interests likely to be advanced by the Institution it was thought better to waive the idea of a professional president." At the start, also, there was an additional reason, associates then far outnumbered professional members. But although that superiority in numbers has long since ceased to exist, the Council has hitherto reaffirmed the view taken fifty years ago, on each occasion when a president has been selected, and it is agreed by all who are familiar with the history of the Institution that this practice has given excellent results. Public men of eminence and high social standing have been ready to assume the office when selected, and many of them have served for long periods.

The first president was Lord Hampton (then Sir John Pakington), who, as First Lord of the Admiralty, had been responsible, in 1859, for ordering the construction of the Warrior, our first sea-going ironclad. For twenty years Lord Hampton held office, taking great interest in the affairs of the Institution, and doing much to promote its claims to public recognition and official support. In 1880 the Earl of Ravensworth succeeded Lord Hampton, and occupied the presidential chair for thirteen years. His intimate knowledge of shipping, and the high regard entertained for Lord Ravensworth by British shipowners and shipbuilders, made his period of office most advantageous to the Institution. When increasing age led Lord Ravensworth to tender his resignation, Lord Brassey became president. His name appeared in the first list of members and associates, and his interest in the Institution had continued for twenty years before his election to the chair. His term of office was unfortunately short, as he was called to the Governorship of Victoria in 1895, and was consequently compelled to resign the presidency. The Earl of Hopetoun became president in 1896, and did good service for five years until he was appointed the first Governor-General of the Australian Commonwealth. The Earl of Glasgow succeeded in 1901, bringing to the post ripe experience gained as an officer in the Royal Navy and Governor of New Zealand. For seven years Lord Glasgow served the Institution faithfully, and then decided to retire. Fortunately the constitution provides for a continuance on the Council of gentlemen who had served as presidents, so that at the present time the two surviving past presidents, Lord Brassey and Lord Glasgow, are still rendering valuable assistance in the management of the affairs of the Institution. Earl Cawdor became president in 1908; and, during the short period which intervened before his much-regretted death, gave evidence of the beneficial influence which his high character and conspicuous ability would have exercised upon the progress of the Institution had his life been spared. At the meetings in April last the Marquis of Bristol was unanimously elected to the presidency. His brilliant career as an officer of the Royal Navy, and the valuable service already rendered to the Institution in connection with the Jubilee celebrations, furnish good evidence that Lord Bristol will prove in all respects a worthy successor to the eminent presidents who have preceded him. It is permissible to hope that his influence will lead to large additions to the considerable number of associates of the Institution who are his brother officers in the Royal Navy.

In regard to election of vice-presidents also the practice of this Institution differs from that of other technical societies. From the first it was thought desirable to solicit the services of a number "of noblemen and gentlemen of great ability and eminence who are or have been closely connected with either the Royal or the Mercantile Navies, and who might be willing to act as vice-presidents." There has never been a lack of eminent men of these classes amongst the vice-presidents; many of them have taken an active part in the management of the institution. With these non-professional vice-presidents have been associated a certain number of professional vice-presidents, whose work as naval architects and marine engineers marked them out for this distinction. Other vice-presidents have been chosen from amongst gentlemen holding high official positions in connection with shipping organisations and from the officers of the Royal Navy. Amongst the latter the name of Admiral Sir John Dalrymple Hay stands pre-eminent, both on account of his connection with the Institution from its earliest days and the valuable services he has rendered.

For thirty years the choice of vice-presidents was practically made by the Council of the Institution, their recommendations having been always confirmed at general meetings of the members. During this long period no limit was fixed to the number of vice-presidents (which finally rose to 30) or to their period of service. In 1890 it was decided to introduce new rules. The maximum number of vice-presidents was fixed at 24; it was also provided that members and associates should have the right of voting by ballot in elections held to fill vacancies in the list, the council nominating candidates for election. This arrangement was continued until 1905, when a new class of honorary vice-presidents was created. In this new class are included gentlemen who occupy distinguished public positions, and others "who have given long and honourable service to that Institution." The Council has the power of election; there is no limit of numbers, and honorary vice-presidents are not subject to re-election annually, as are the presidents, vice-presidents, and treasurer.

Elected vice-presidents now number 16; when vacancies occur the Council nominates a list of candidates, and the members elect, as before, by means of ballot-papers. It will be seen that this arrangement provides for transfers from the list of elected vice-presidents to that of honorary vice-presidents, and so creates vacancies on the former list. Experience has shown that this plan promotes the interests of the Institution; there was previously no natural flow of promotion like that which results from the periodical advancement of vice-presidents to the presidential chair in other technical societies. All vice-presidents in both classes are entitled to sit and vote with the members of the Council, and actually take an important part in the proceedings.

Members of Council have included from the first representatives both of professional members and of associates. As the latter class constituted the larger proportion of the vice-presidents, it was decided to limit its further representation on the Council to about one-fourth of the representation given to professional members, but in the conduct of business of the Institution associates have always taken, and still take, a prominent and useful part. From the beginning there has been a considerable representation on the Council of professional officers serving at the Admiralty and the Royal Dockyards. Lloyd's Register of Shipping has also been represented from the first. In recent years the British Corporation and the Veritas Society have also been represented; and as time has passed and the interest of private shipbuilders and marine engineers has increased, their representation on the council has been much enlarged, with great advantage to the Institution.

During the first 20 years the members of council varied from 25 to 30, and the associate members from six to seven. In 1879 it was decided to fix the maximum for each class at 24 and 6 respectively. Up to that date the Council had practically co-opted new members, the list of nominations being presented *en bloc* to the general meetings, and adopted as a matter of course. It was then felt to be desirable to give the members and associates of the Institution a more direct voice in the election, and rules were made by which a nomination list was prepared each year by the Council, and a system of ballot-papers was introduced by means of which the votes were given. Nine years later it was determined that instead of an annual election of the whole Council there should be an annual retirement by seniority of six ordinary members and two associate members, who remained eligible for re-election; the ballot-lists for the election of their successors containing as many new names in each class as there were retirements. In 1905 it was decided to increase the members of the Council to 36 ordinary members and 12 associate members; nine of the former and three of the latter who had served longest on the Council retiring annually, and being eligible for re-election. That regulation still holds good, and under it the Council, including the president, past-presidents, vice-presidents, and honorary vice-presidents, has become a very large body, but it still remains effective, and is fully representative. When the new rules were presented to and approved by the members and associates of the Institution in April, 1905, the following statement was made:—"This Institution is the central institution of a great industry which is scattered all round the coast of this island, and the sister island—Ireland. It is a scattered constituency, and we wish always to have represented on the Council the various districts where shipbuilding and marine engineering are practised. It is of the greatest value to this Institution that such a system of local representation should be continued and extended, and that is always kept in view by the Council in making nominations of new candidates for the Council. We also wish to have both naval architecture and marine

engineering adequately represented. On the associates' side are included many classes in the community. We have shipowners, naval officers, representatives of great shipping institutions, yachtsmen, and scientific men interested in the practice and theory of shipbuilding and engineering. For all these reasons the Council have judged that it is desirable to make the changes described."

(To be continued.)

PROGRESS OF NAVAL CONSTRUCTION IN JAPAN.*

By Rear-Admiral MOTOKI KONDO, Inspector-General of Naval Construction, I.J.N., Member.

THE fact that the art of shipbuilding is not entirely modern in Japan was well illustrated by the models and pictures of our ancient war galleys which were on view last year at the Anglo-Japanese Exhibition. In this paper, however, I do not propose to go back to so remote a period, and I shall only deal with the progress of our naval construction since the introduction of European methods of shipbuilding in Japan.

It is interesting to mention in this connection that the keel of the first warship of this type ever built in Japan was laid in 1861, and it will thus be seen that our modern navy is nearly as old as this Institution.

I shall first give a brief account of the development of our naval dockyards, and then deal with the progress of naval construction in our country.

Navy Yards.—We have at present four navy yards—viz. :—Yokosuka, Kure, Sasewo, and Maidzuru, besides three smaller repairing yards at Ominato, Takeshiki, and Bako.

The Yokosuka Navy Yard is the oldest establishment of this kind in our country. It is situated in the Bay of Tokyo, not very far from the entrance to the bay, and was commenced in 1864 under the superintendence of the Tokugawa Regency. The technical staff at the time consisted entirely of French naval constructors, with their own foremen and leading hands under them, lent by the French Government.

At first the yard was not intended exclusively for naval work ; in fact, it was a sort of general shipbuilding yard. Subsequently this place passed into the possession of the Imperial Government, and was worked for some years under the direct superintendence of the Ministry of Public Works (since abolished), until, in 1872, it was transferred to the Imperial Navy, by whom it continues to be worked to this day.

TABLE I.—*Number, Aggregate Displacement, and Horse-Power of Warships Launched in Japan.*

Year.	Number	Displacement in Tons.	Horse-Power.	Remarks.
1890				
1891	2	4,908	6,100	A cruiser and a gunboat.
1892	1	3,126	7,500	A cruiser.
1893				
1894				
1895	1	2,657	8,500	A cruiser.
1896	2	1,772	6,000	A despatch boat.
1897	1	2,756	8,000	A cruiser.
1898				
1899				
1900	1	1,238	6,000	A despatch boat
1901				
1902	2	6,732	18,800	Two cruisers
1903	2	3,620	11,000	A cruiser and a gun-boat
1904				
1905	1	13,750	20,500	An armoured cruiser
1906	2	32,950	40,000	A battleship and an armoured cruiser
1907	5	54,350	44,000	A battleship, two armoured cruisers, a cruiser, and a despatch boat. Turbines for two ships made abroad
1908	1	1,350	..	A despatch boat. Turbines for one ship made abroad
1909				
1910	1	20,800	25,000	A battleship

Total since 1890, 22.

TABLE II.—*Number, Aggregate Displacement, and Horse-Power of Torpedo Craft Built in Japan.*

Year.	Number	Displacement in Tons.	Horse-Power.	Remarks.
1900	6	3 '1	4,200	All torpedo-boats.
1901	3	162	2,100	,, ,,
1902	5	981	15,100	3 destroyers ; rest torpedo-boats
1903	17	2589	16,200	2 ,, ,,
1904	4	331	18,600	1 ,, ,,
1905	12	4500	72,000	All destroyers.
1906	18	6750	108,000	,, ,,
1907	2	750	12,000	,, ,,
1908	1	375	6,000	Destroyer.
1909	1	375	6,000	,,
1910	1	1150	20,500	,,

But to return to the history of the establishment : the first sod was turned on September 27, 1865, and the first foundation-stone for the buildings was laid in March the next year. The first graving-dock was formally opened on February 7, 1870. Prior to 1885 all the ships launched in this yard were built of wood, but in this year the first composite ship, H.I.M.S. Katsuragi, was launched. H.I.M.S. Atago was the first iron ship built in this yard, and was launched in 1887. After this the progress of shipbuilding went on steadily, and after building several

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 5, 1911.

TABLE III.—LIST OF WARSHIPS BUILT IN JAPAN.

Year Launched.	Name.	Where Built.	Displacement.	Type.	Material of Hull.	Machinery Particulars.	Propeller.	Remarks.
1862	Chiyoda	Ishikawajima	140	Gunboat	Wood	Direct-acting geared	Single-screw	Sold.
1875	Seiki	Yokosuka	897	Sloop of war	,,	Three-cylinder compound horizontal	,,	Lost off mouth of Fujikawa.
1876	Jingei	,,	1,450	Imperial yacht	,,	Diagonal	Paddle	Broken up.
1877	Amagi	,,	911	Sloop of war	,,	Three-cylinder compound horizontal	Single-screw	Sold.

1907	Kurama	Yokosuka	14,600	Armoured cruiser	,,	Triple expansion vertical	,,	
1907	Tone	Saseho	4,100	2nd-class cruiser	,,	,, ,, ,,	,,	
1907	Yodo	Kobe	1,250	Despatch vessel	,,	,, ,, ,,	,,	
1907	Ibuki	Kure	14,600	Armoured cruiser	,,	Turbine	,,	
1908	Mogami	Nagasaki	1,350	Despatch vessel	,,	,,	Triple-screw	
1910	Kawachi	Yokosuka	20,800	Battleship	,,	,,	Twin-screw	

third-class cruisers, besides smaller craft, the first battleship ever built in Japan—H.I.M.S. Satsuma—was launched in 1906.

At present the dockyard has two large building-slips and three smaller ones, for destroyers and torpedo-boats. The largest slip has a gantry fitted over the whole length, provided with several cranes ranging up to 30 tons. The graving-docks are four in number, and the largest one is capable of taking ships of the largest dimensions now afloat.

The following figures will give some idea of the enormous growth of this place since it was first started :—

The number of workmen was only 960 in 1869, while we now have over 8000 all told. The extent of the grounds, which was but 21,700 tsubo (about 18 acres) in 1865, is now more than six times what it was then, being over 140,000 tsubo (about 116 acres).

The engineering department consists of foundry, smithy, machine-shop, boiler-shop, plumber's shop, &c. ; it is, in short, replete with all the appliances necessary for the construction of the heaviest engines and boilers for modern warships. The whole of the propelling machinery of H.I.M.S. Satsuma was made here, including the whole of the castings, all the important forgings, and the entire machining, as well as the water-tube boilers, which are of the Miyabara type. Even most of the auxiliary machinery was made here.

A good deal of repair work is also performed in this dockyard, and for a few years after the late war the place was very busy indeed, on account of alterations and repairs of captured ships that had to be executed over and above the new construction and ordinary repairs and overhaul of our own ships, and the number of workmen employed at the time was more than double what it is now.

The Kure Navy Yard, the second oldest yard in Japan, is situated in the Inland Sea, near Hiroshima. It was commenced in 1889, but it was not until just before the Chinese war that the place became of any very great importance. It has since been gradually developed, and at the present time it rivals Yokosuka Navy Yard in the extent of site, as well as in the amount and the quality of work turned out. There are two large building slips (one of them fitted with a gantry throughout the length of the slip), besides smaller ones for destroyers and torpedo-boats. There are two graving docks now in use and two more of larger size are under construction.

Seven warships and fifteen destroyers and torpedo-boats were built here during the last sixteen years, and to this dockyard belongs the honour of having turned out the first armoured vessel built in our country. It also holds the record for the quickest construction, having launched H.I.M.S. Ibuki in exactly six months after laying down the keel.

The engineering department here is on a similar scale to that in the Yokosuka Navy Yard, and the work turned out is fully equal in amount and quality to that of the latter place.

The ordnance department in this yard has the capacity for manufacturing guns and mountings up to the largest size, and almost the whole armament of all the warships built in Japan of late years has been made here. There are steel works and armour-plate works also belonging to this yard.

The Sasewo Navy Yard is in the Island of Kyushu, not very far from Nagasaki, and was started in 1890, but very little progress was made until just before the Chinese war. This yard is primarily intended for repair work. There are five large docks, of which three are under construction, and one small dry dock for minor craft. Besides the necessary appliances for all kinds of repair work, the dockyard has facilities for new construction, and has already built one second-class cruiser, and several destroyers and torpedo-boats fully equipped and engined. At present one second-class cruiser, Chikuma, of about 5000 tons, is approaching completion in this yard, being launched last April.

The Maidzuru Navy Yard is the most recent of our Navy yards, having been formally opened in 1901. This is the only yard we have at present in the Sea of Japan, and it is within easy reach of Osaka and other important towns by railway. This yard is also well equipped with appliances for repair work, as well as for new construction. So far, only six destroyers have been built here, but the place is fully equal to heavier work if required. There are two large (one building) and two small graving docks.

There are also three small navy yards in the auxiliary naval stations at Ominato, on the north-east coast ; at Takeshiki, in the Island of Tsushima ; and in Bako, in one of the islands of Pescadores. These yards are only intended for minor repair work, mostly for destroyers and other small craft, and the number of workmen employed is very small. There is a small floating dock for lifting ships up to about 1500 tons in each of the two first-mentioned yards, and there is a small dock in course of construction at Bako.

Ship Construction.—The first warship on the European model ever built in Japan was a small screw schooner called Chiyoda Gata (Fig. 1, page 16). She was built under the jurisdiction of the Tokugawa Regency at Ishikawajima, at the site now owned by the Ishikawajima Shipbuilding Company, situated on a delta in the mouth of the River Sumida. Her keel was laid on May 7, 1861, she was launched on July 2 the following year, and was completed in May, 1863. Her engines and boilers were constructed in the Shogun's workshop in Nagasaki, probably on one of the sites now belonging to the Mitsubishi Dockyard. It is interesting to note that not only her hull and fittings, but the whole of her machinery, were constructed by native workmen with the native materials, under the directions of Japanese officers, who were also responsible for the design.

Her principal particulars are as follows :—

Material of hull	Wood
Length between perpendiculars	97 ft. 4 in.
Breadth, extreme	16 ft.
Draught of water, mean	6 ft. 8½ in.
Displacement in tons	140
Indicated horse-power	60
Speed in knots	5
Boilers	Two multitubular
Engines	Direct acting, geared
Diameter of cylinders	Two 16-in.
Stroke of pistons	15¾ in.

This little gunboat saw active service during the civil war against the present Government, but was inadvertently run ashore and abandoned. She was ultimately refloated and captured by the Government forces. After serving several years in the Imperial Navy, she was transferred to a whaling company, who, I believe, have her still in service.

After this boat was built, no important naval construction was attempted for a considerable period, all the ships being acquired from abroad, and it was not until

the Yokosuka Navy Yard was in full swing in naval hands that attention was again drawn to this important branch of industry.

H.I.M.S. Seiki (Figs. 2 and 3) was the first warship built at Yokosuka Dockyard, and may be considered as the pioneer of all the warships built in our country. She was laid down on June 20, 1873; launched on May 5, 1875; and completed in June, 1876. She was built of wood, and was designed by M. Verny, the head of the French naval architects in the yard, and was built and engined by the French naval architects and engineers.

Particulars of H.I.M.S. "Aki" and "Kurama."

	"Aki."	"Kurama."
Type	First-class battleship	First-class armoured cruiser
Where built	Kure Navy yard	Yokosuka Navy yard
Date of launch	1907	1907
Length between perpendiculars	460 ft.	450 ft.
Breadth extreme	83 ft. 6 in.	75 ft. 6 in.
Depth	44 ,, 6 ,,	42 ,, 3 ,,
Draught	27 ,, 6 ,,	26 ft.
Displacement in tons	19,800	14,600
Horse-power	24,000	22,500
Type of machinery	Curtis turbines	Triple-expansion vertical engines
Speed	20	21¼
Armament	4 12-in. guns. 12 10-in. guns. 8 6-in. guns. 8 12-pdr. guns. 4 Maxim guns. 5 18-in. torpedo tubes.	4 12-in. guns. 8 8-in. guns 14 4.7-in. guns. 4 12-pdr., 3 3-pdr. guns. 4 Maxim guns. 3 18-in. torpedo-tubes.
Protection	9 in. belt. 2-in. deck. 9-in. barbette.	7-in. belt. 1½-in. deck. 7-in. barbette.

The first composite ship built was H.I.M.S. Katsuragi. She was built at Yokosuka, and launched in 1885. She is a sloop-of-war of 1400 tons displacement, and is still doing service as a surveying vessel. During the construction of this vessel two foremen were lent by the British Government to initiate the Japanese workmen into the mysteries of manipulation of iron plates and bars.

The first iron ship, H.I.M.S. Atago, was also built at Yokosuka, and was launched in 1887. She was a gunboat of 612 tons displacement and 10 knots speed. She was lost during the late war, being run on rocks in a heavy fog. After this period practically all the ships built for the navy were of steel, ranging from gunboats to second-class cruisers in type and from 1250 tons to 4160 tons displacement. Until the laying down of H.I.M.S. Tsukuba in the Kure Navy Yard in 1904, which marked the new epoch in our naval construction, no ship of larger size than an unarmoured cruiser of a little over 4000 tons had hitherto been built, while this ship is an armoured cruiser of 13,750 tons. This event was all the more notable for the fact that she was commenced during the Russian War, and was the most powerful armoured cruiser in the world at the time, a position she held until the advent of the cruisers of the Invincible class. No doubt many of the members of this Institution will remember that she was one of the ships sent by the Japanese Government to take part in the Columbian Fête at Hampton Roads, and since then sent over to England in 1907.

The first battleship built in Japan was H.I.M.S. Satsuma, laid down in 1904 at Yokosuka, and she was the heaviest warship in the world at the time of her launch. She is now practically complete, having passed through her steam and gunnery trials successfully.

At the Kure Navy yard H.I.M.S. Aki was commenced in the same year. She is practically a sister-ship to the Satsuma, but is a little larger, and slightly more heavily armed. She will be finished in the course of the year.

A few particulars of H.I.M.S. Aki (Figs. 4 and 5) and H.I.M.S. Kurama (Figs. 6 and 7, page 17), an armoured cruiser built in Yokosuka, are given in the previous column.

Two battleships, the Kawachi and Settsu, of over 20,000 tons are under construction, the former at Yokosuka and the latter at Kure. They were launched last October and March respectively. A large armoured cruiser of 27,500 tons has also just been commenced at Yokosuka.

With regard to the torpedo-craft, we have had several torpedo-boats in service for years, but they were all ordered from abroad, being built up, taken to pieces, and sent over to Japan and rebuilt at home, and it was not until late years that we began to design and build these boats ourselves. In 1899 a third-class torpedo-boat was commenced at Yokosuka Dockyard, and three years later first-class boats were also laid down in Kure and second-class boats in Yokosuka and Sasewo. Since then altogether twenty-two boats of this class have been built in Japan.

The first destroyer built in our country was the Harusame, laid down at Yokosuka dockyard in 1902. She proved to be a very successful boat, and in all thirty-nine boats of this class have since been built in our dockyards and private yards. We have been singularly fortunate in their steam trials, as they have not only attained the estimated speed without difficulty, but we were exceptionally free from mishaps, only one instance of any serious accident occurring during the whole time, and even then there was no loss of life. At present we have two destroyers of 1150 tons displacement under construction, one at Maidzuru and one at Nagasaki.

Naval Construction in Private Yards.—At present we have two large private shipbuilding yards in Japan, capable of turning out the heaviest warships complete with their machinery. These are the Mitsubishi Dockyard, Nagasaki, and the Kawasaki Shipbuilding Company, Kobe. In the former, H.I.M.S. Mogami was built, complete with her turbine machinery, and they are at present building a second-class cruiser and a large destroyer for the navy. In the latter place, the despatch-boat Yodo and several destroyers and torpedo-boats were built, and they are building a second-class cruiser, a sister vessel to the one building at Nagasaki. Orders have just been placed with each of these firms for the construction of a large armoured cruiser, similar to the one building at

Yokosuka. Besides the above there are also several smaller firms capable of constructing destroyers and smaller craft, with the engines and boilers complete. Among these the Osaka Shipbuilding and Engineering Company, Osaka, and the Uraga Shipbuilding Company, each built two destroyers for the navy, and the H.I.M.S. Chokai, the sister-ship to the Atago, already mentioned, was built at Ishikawajima.

Personnel.—In the early years of Meiji (from the end of the 'sixties to the early 'seventies) when young students were sent abroad to study different branches of the naval profession, some of them were told off to investigate naval construction in its theoretical and practical aspects, and they made their studies in England and Scotland. Soon after this several young students were also sent to France for a similar purpose, and thus the nucleus of the naval constructors in our navy was formed. In the meantime the class of naval architecture was founded in the Imperial College of Engineering (under the Ministry of Public Works, since abolished), and some of the graduates entered the navy. After this a few graduates joined the navy each year, the college being since amalgamated with the Tokio University under the name of the Imperial University (under the Ministry of Education). Under the present *régime* one or two students of naval architecture are selected each year, and a special additional education given them by naval constructors to enable them to fit themselves for the service requirements. These students on graduating from the university are appointed assistant-constructors (ensign's rank) and enrolled in the Corps of Naval Constructors.

Until 1887 all naval constructors were civilians, but in that year a special military rank was formed for the technical corps, and naval constructors, constructing naval engineers, and ordnance constructors, were enrolled in this corps. In 1894 this branch was again subdivided into separate corps of naval constructors (naval construction and naval engineering) and ordnance constructors (including torpedo branch). At present constructors have similar ranks to other branches of naval officers, and follow the same regulations as to promotion, scale of pay, &c. They wear uniforms similar to the other non-executive branches of naval officers (the distinguishing colour of the piping being brown for the naval constructors and chocolate for the ordnance constructors).

The corps now comprise the following :—

	Corresponding Rank.
5 Inspectors-General.	Rear-Admiral.
6 Chief Inspectors.	Captain.
6 Inspectors	Commander.
24 Chief Constructors.	Lieutenant-Commander.
25 Constructors.	Lieutenant.
8 Assistant Constructors.	Ensign.
Total 74	

There are also several civilian officers employed on special duties. In the engineering branch several naval engineers are also employed along with the constructing engineers. These officers are given special instruction for the purpose.

It may be mentioned here that many of the officers, after leaving the college and serving in the dockyards for some years, were sent abroad for further studies in the profession, and several have gone through the regular course of naval construction in the Royal Naval College, Greenwich, in England, and l'Ecole d'Application du Génie Maritime, in France, through the courtesies of their respective Governments.

With regard to the workpeople, we have now a goodly number of skilled men available throughout our country, but formerly there was absolutely no source to draw upon. In fact, it is not too much to say that we had not only to bring up workmen for employment in our own naval works, but also for private firms, who had no other means of obtaining them. In this respect we were in an entirely different position from that which obtains in Great Britain and other European countries, inasmuch as, while in these countries private enterprise first developed, and very often the Government reaped the benefit thereof, in our country the Government had to take the initiative in nearly every industry, and naturally the workmen had to be trained in the Government works also. Of course these men were not expressly trained for the purpose of turning them over to private yards, but when they wished to leave the Government works to go to the private ones we never placed any very great restrictions in their way.

We have a class of men who rank between the foremen and the commissioned officers. These non-commissioned officers are civilians and are either chosen from leading hands who have shown a special aptitude in their trade, and also have the necessary education for the post they are to occupy, or are taken from the graduates of certain technical schools (with whom special arrangements had been made) after serving a certain period of time as ordinary workmen.

The number of workmen engaged in the naval construction and marine engineering in the Imperial Dockyards at the end of 1910 was as follows :—

	Shipbuilding.	Engineering.	Total.
Yokosuka	4,562	3177	7,739
Kure	3,551	2342	5,893
Sasewo	2,101	1839	3,940
Maidzuru	1,241	1378	2,619
Ominato	71	67	138
Takeshiki	124	97	221
Bako	61	65	126
Total	11,711	8965	20,676

We hear a good deal about the Japanese people being able to adapt themselves to new ideas and new methods, but the fact should not be lost sight of that the Japanese have always been well up in all branches of handicraft. Several branches of industry had reached a very high state of proficiency before the intercourse with the Western nations, and, although the extensive use of machinery was certainly new to our ideas, no great difficulty was experienced in adapting ourselves thereto. As a rule, our men are intelligent and versatile, and it was a comparatively easy matter to train them in different branches of shipbuilding and engineering.

On this account our men are peculiarly suited for delicate work, as, for instance, in the construction of hull and machinery of torpedo craft, which may account for the fact that these craft can be built at very much less cost at home than abroad.

We are at a great discount on account of lack of physique of our men where much manual labour is required, and thus we derive a great benefit from the modern inventions for dealing with heavy materials. Just to give an instance of the great saving in labour through the use of transporting appliances, I may cite the cases of H.I.M.S. Tsukuba and H.I.M.S. Ikoma, built in Kure before, and H.I.M.S. Aki, built after the installation of the gantry crane. While the latter ship is of some 6000 tons more displacement than the former, the amount spent on labour up to the time of launching for the latter ship was actually less than the corresponding figure for the two former.

I might mention, in passing, that our working hours are somewhat longer than those in British yards, being on the average about 9½ hours per day. The scale of pay is still very low, the average rate (including labourers) being rather under 1s. 6d. per day, or 9s. per week;

but it is rising by leaps and bounds; it has more than doubled in the last ten years. The premium system is adopted to a limited extent for some work, and, so far, it seems to work without any obstacles.

Armour-Plate Manufacture.—The plant for the manufacture of armour-plates was first started in 1902 in Kure Navy Yard. After a certain period of time spent in experiments, &c., we are now able to produce armour-plates of reliable quality, and the output is fully equal to all our requirements for some time to come. I am not able to give a description of the process employed, as it is outside my profession; but I understand it is a special process invented by our own engineers, and, according to the results of the firing trials and physical and chemical tests conducted from time to time, the quality is fully up to the best armour-plate of the day.

I am pleased to say that, only three years after the works were started, plates of sufficiently reliable quality were turned out to justify their adoption on H.I.M.S. Tsukuba. In this respect the expectations of the most optimistic were surpassed.

Experience Gained during the late War.—One is apt to attach too much importance to the experiences gained during the war. No doubt much valuable information was obtained in tactical and strategical matters, though even there, I fear, much has been left unsolved. In naval construction, at any rate, I find that many questions we were anxious to have solved by war experience remain unsolved to this day. When we come to consider the number of times that actual battles took place during nearly a year and a half that the hostilities continued, we can easily understand that it is impossible that all the innumerable possible cases should take place. It is true that we have received confirmation of what we deemed most probable, which we could never have ascertained in peace time, but in the main it is safe to say that no new lessons have been learned by the war to revolutionise the art of naval construction. The Dreadnought is but the logical outcome of the progress of naval construction, and that type would have been arrived at sooner or later, even if the war had never taken place.

One point, however, which has been brought home forcibly to all, and to naval architects in particular, is the danger from fixed and floating mines. Even in this case the idea of protecting the under-water portion of the ship is new, as the Cesarevitch, built nine years ago, had a torpedo protection embodied in her construction; and if we provide the protection to the new ships, it can but be the development of the ideal first adopted in the Cesarevitch.

In minor points about equipments and fittings we have naturally gained considerable experience, but they are too numerous and trivial to be mentioned in a paper dealing with such broad subjects.

On pages 15 and 16 are tables, and on page 17 diagrams, which may help to show the progress of naval construction in Japan.

FIFTY YEARS' CHANGES IN BRITISH WARSHIP MACHINERY.*

By Engineer-Vice-Admiral Sir HENRY J. ORAM, K.C.B., Vice-President.

THE general progress of engineering in H.M. Navy from 1860 to 1897 has been previously dealt with in a paper read by two of our vice-presidents, Sir John Durston and Mr. Milton, at the international congress of this Institution in 1897, while a great deal has been written on the subject in various other papers, so that the scope for any additional or original *résumé* of events previous to 1897 is limited.

At the request of the Council, however, I have endeavoured to indicate more fully the conditions of naval engineering in 1860, and generally the changes and progress made during the fifty years' existence of this Institution.

In 1860 the Navy List included the following numbers of steamships, with propelling machinery manufactured by various firms between 1842 and 1859—132 ships of 400 nominal horse-power and upwards (including 23 paddle-ships), and 367 ships below 400 nominal horse-power (including 87 paddle-ships), giving a total of 499 ships, with a collective nominal horse-power of 116,540, or about 540,000 indicated horse-power.

In 1910 the number of warships was 585, but with a much increased total horse-power—of approximately 5,000,000.

The founding of this Institution coincided with the period when the definite abandonment of the paddle-wheel as the means of propulsion of warships had occurred and the screw had been adopted for propulsion. In all the warships built in 1860 screw-propellers were arranged for.

The earliest ships with screw-propellers had engines designed on the same lines as those fitted in paddle vessels and working at low revolutions. These were adapted to drive the screws by means of gearing, which increased the revolutions of the screws as compared with those of the engine; but in 1860 gearing had been dispensed with, and the engines on order were of the horizontal type, and designed to drive the screw direct, the revolutions of the engines being increased accordingly. These engines worked at from 34 to 105 revolutions per minute at full power, with piston speeds varying from 200 ft. to 550 ft. per minute.

All these earlier ships were fitted with jet condensers, except in the case of the small gunboats, which had non-condensing engines, the exhaust steam being discharged up the funnel. Stephenson's link motion for actuating the slide-valve and for reversing the engines was usually fitted, and it may be remarked that some form of Stephenson's link motion has remained as the standard valve-gear for reciprocating engines up to the present time. Many of the larger ships were provided with separate expansion valves.

The boilers under construction in 1860 were generally of the box tubular form, working at a steam-pressure of about 20 lb. per square inch, the earlier box-flue boiler having been discarded. The gunboats with non-condensing engines were, however, fitted with the low cylindrical type of boiler designed for a steam-pressure of 60 lb. per square inch.

At such early stages in the application of steam to warship propulsion during the transition period from paddles to screw, with a gradually rising steam-pressure, one would naturally expect a few mistakes to be made, and at this period there were cases of comparatively new screw ships which had their original engines and boilers removed and either converted, sold, or broken up, new engines and boilers being fitted. Many installations of copper boilers were also removed and replaced by iron ones.

Table I., page 20, has been prepared to show the leading particulars of the engines and boilers fitted in representative warships during the period covered by the existence of this Institution. The powers given and the figures based on them refer to those developed on the usual eight hours' trial, as these are more suitable for the purposes of this paper; the increase of power obtained by extra forcing of the boilers for shorter periods are neglected. Some of the earlier ships, however, for which the figures have been inserted, had trials of only two hours', or even less, duration. It must be understood, therefore, that most of the ships in the table, especially the later ones, can exert considerably more power for shorter periods than has been stated.

The warship fitted with the most powerful machinery in 1860 was the Warrior. She was described as a shot-proof frigate, and had engines of 1250 nominal horse-power. The machinery developed 5469 indicated horse-power on trial, giving the ship a speed of 14.3 knots. The engines were of Penn's trunk design of the simple-expansion type, with two cylinders. Each cylinder was fitted with a separate expansion-valve. The revolutions on trial were 54.25, which, with a 4-ft. stroke, gave a piston-speed of 434 ft. per minute. Metallic packing-rings were fitted to the pistons, the specification stating that they should be constructed "so as not to require the use of hemp or other packing behind them." There were two jet condensers, one for each cylinder, with double-acting air-pumps, which, with the feed-pumps and fire and bilge pumps, were worked directly off the main engine pistons. The boilers were of the box tubular type, and the dead-weight safety-valves were loaded to 22 lb. per square inch. The furnaces and tube-plates were specified to be of Low Moor or Bowling iron, two qualities of wrought iron which were familiar in Admiralty specifications until the introduction of wrought steel for such parts. The tubes were of brass, and it was specified that every part of the boiler was to be in contact with water or steam. The fire-grate was 900 sq. ft. in area, the boiler heating surface 22,500 sq. ft., and on trial 6.08 horse-power was obtained per square foot of grate.

This ship was fitted for working entirely under sail, and to suit the sails the funnel and waste-steam pipes were telescopic, and the gun-metal screw-propeller was of the lifting type, easily disengaged from the driving shaft. Cast iron, wrought iron, and gun-metal were the usual materials of this period; Muntz metal was used for pump rods, and white metal was allowed to be used "where desired." The specified time for completing the work ready to be put on board was eleven months, and the further time for fitting in the vessel was three months. As first fitted, the engines were reversed by hand gear; hand power was also used for steering the ship and working the capstan. Steam-engines were subsequently fitted in the ship for all these purposes, the first to be supplied being a steam capstan engine. The hull of the Warrior is still in existence as a hulk employed as a floating workshop in connection with H.M.S. Vernon.

Of the types of marine engines manufactured in 1860 the principal were those of the three leading makers, and distinguished by the names of these firms:—

Messrs. Maudslay.—This was a double piston-rod engine, with piston rods over and under the crank-shaft communicating with crossheads and guides fitted on the opposite side of the crank to that of the cylinder. This design was known as the "return connecting-rod" engine, and with the single screw then fitted allowed the horizontal engines to have a longer stroke and connecting-rod.

Messrs. Penn.—The trunk engine made by this firm was a favourite type, the absence of a piston rod making a short engine, well suited for the space available in a single-screw ship. Although with the lower pressures these engines worked remarkably well, difficulties with the trunk became pronounced as the steam pressure rose, and ultimately led to the abandonment of this type.

Messrs. Humphrys.—A development of the above design (Messrs. Humphrys, Tennant and Co.) consisted of leading one piston rod to a crosshead, from which rods were passed to the crosshead and guide on the opposite side of ship to that of the cylinder. This design, therefore, also had the return connecting-rod. The design, however, which is principally associated with the name of Messrs. Humphrys, is the direct-acting engine, having the connecting-rod between the cylinder and the crank, the disadvantages of the shorter connecting-rod being accepted. This design of Humphrys was the prototype of the direct-acting engine which ultimately became universal, and, as the introduction of twin screws allowed of longer strokes being arranged for, the direct-acting engine of the horizontal type with connecting rod between the cylinder and the shaft became the universal practice from about 1871 until the introduction of the vertical engine.

In the Appendix there are extracts from the report of an Admiralty Committee of 1858, giving their opinion on the relative merits of these types.

The horizontal engine had an advantage over the vertical type, in that it allowed the engines to be placed below the water-line, but a disadvantage existed in the large amount of floor space necessary. The highest powered horizontal engines were those of the Melpomene class of 9000 indicated horse-power ordered in 1887. At this time the engines used were of the triple-expansion type, with steam-pressure of 155 lb. per square inch. These engines obtained their large power by an increase of the steam pressure and of the revolutions, but they were by no means the largest horizontal engines in size, as will be seen by reference to Table I., page 20.

The change from the horizontal to the vertical type was made in 1885 for the large ships, but sloops and gunboats continued to have horizontal engines till 1887-8. With the further rise of boiler pressure in 1887 came the fitting of triple-expansion engines, which at first were of the three-cylinder design; but, as powers increased, the low pressure cylinder was divided to reduce the size, and the four-cylinder triple-expansion engine became common.

The more important improvements effected during the last fifty years have been in the direction of economy of fuel, and reduction of weight of machinery and of the space occupied by it. Concurrently with these advantages increased life and reliability of the machinery have been obtained by attention to details of construction and quality of workmanship and material.

Much has been done to satisfy the constant demand for reduction in weight by the selection of stronger materials for the more heavily stressed parts, and improvements in the method of producing the materials used has resulted in stronger and more reliable metal being available. This latter development includes, in the period under review, the invention of the Siemens furnace and the production of mild steel of reliable and uniform quality in forgings, plates, and castings; the manufacture of high-class seamless steel tubing for boiler-tubes and steam-pipes; the production of corrugated and other similar forms of furnaces, high-tension bronzes, metallic and asbestos packings, and other devices required for high-pressure steam. There has also been a multitude of improvements in machine tools, some of which, such as forging presses, riveters, flanging machines, welding plants, gauges, and measuring machines for securing accuracy of workmanship, have been essential to the turning out of high-class work, and have made possible many of the advances now under review; many others, if not essential to actual construction, have had a marked effect on rapidity of production and reduction of cost.

Improvement in economy has been chiefly effected by successive increases of steam pressure, although, in the early stages, the introduction of steam jackets and superheaters produced some direct saving at the lower pressures. Table II., page 21, shows how improvement in economy has accompanied the rise in steam pressures.

The earlier increases in steam pressures were closely connected with the type of condenser in use, for as soon as the surface condenser was successfully introduced, enabling the boiler to be supplied almost entirely with fresh feed water, the incrustation from deposits of lime and other salts was largely prevented. The liability of overheating the boiler-plates was thus diminished, allowing the pressures to be increased without danger to the heating surfaces.

It is worthy of note that the surface condenser was not a success on the first application, and was dropped for a time, being later reintroduced. Between 1860 and 1870 a large number of engines with surface condensers were fitted in vessels of the Royal Navy, the steam pressure being slightly increased, and being usually about 30 lbs. per square inch.

The simple-expansion engines of about 1870, with steam of 30 lbs. pressure, and fitted with steam jackets, superheaters, and surface condensers, were fairly economical, and were a considerable advance on those immediately preceding them. After the success of the surface condenser, renewed attention was given to the subject of higher steam pressure and the economy due to greater expansion, the theoretical consideration of which marked it out as promising greatly increased economy, if the practical difficulties could be overcome. When the steam pressure rose from 30 lbs. to 60 lbs., the type of boiler changed from the box to the cylindrical, so that this increased steam pressure could be safely carried, and the engine changed to the compound type.

Great difference of opinion existed among engineers as to the merits of the compound system, and probably no change made in marine engineering was the subject of greater controversy. Like the surface condenser, its first application; was made under unfavourable circumstances; in subsequent examples under more favourable conditions the system was remarkably successful, and became universal for marine purposes. It may be mentioned that some of the unsuccessful compound engines were fitted with steam pressure of only 35 lb. per square inch.

In the compound engines the steam jacket was retained as beneficial, but the superheater was abandoned. Superheaters were commonly fitted at the beginning of the period under review, and, although they were probably more of the nature of steam-driers, they were effective in their application, yet the difficulties encountered led to their ultimate complete abandonment.

The gain in economy, which resulted by the use of compound engines using steam of 60 lb., pressure, over the best previous type of simple surface-condensing engines using 30 lb. pressure was from 30 to 35 per cent. This was well authenticated, and represents the average of the replies

* Paper read at the Jubilee meeting of the Institution of Naval Architects, July 5, 1911.

given by the principal engineers and steamship-owning companies to questions of the Admiralty Committee which sat in 1872 on designs of ships of war.

After about 1872 the new engines for ships of the Royal Navy were of the compound type. The original steam pressure of 60 lb. per square inch was increased about the year 1880 to 90 lb., and then rapidly rose to 120 lb. per square inch, the ratio of the cylinder areas being increased with the steam pressure, so as to secure the full benefit from the greater expansion of steam.

After the practical success of one or two vessels fitted with triple-expansion engines, the ordinary compound engine was abandoned in favour of the former type. The success of this design, in association with higher pressures, is undoubted, and from 1885, with a few minor exceptions, all new reciprocating engines for the Navy have been on the triple-expansion principle, with steam pressure commencing at 130 lb. and increasing to 155 lb. per square inch in 1887. A further gain in economy of about 15 per cent. was thus effected.

This period saw the introduction of the evaporator for producing fresh water for make-up feed purposes. The rise of steam pressures and increased duty demanded from boiler-heating surfaces were rendering it necessary to avoid the introduction of any water which would produce even a small deposit on the heating surfaces.

The evaporator, by making it possible to use only fresh water in the boilers, cleared the way for further rises of pressure. These rises of pressure and the demands for reduction in weight and space allowed for machinery finally led to the introduction of the water-tube boiler, the satisfactory use of which at sea had now been made possible by the adoption of the evaporator.

For several years after 1887 the pressure was not advanced beyond 155 lb., except in the case of the torpedo gunboat Speedy, which worked at a pressure of 210 lb. per square inch, the steam of this pressure being generated in water-tube boilers of the Thornycroft type. This vessel is noteworthy as being the first fitted with water-tube boilers on a considerable scale in the British Navy. The pressure was gradually increased still further, until, in 1895, several cruisers were ordered with an engine-pressure of 250 lb. per square inch. This is the maximum pressure for which machinery installations for the Royal Navy have been designed.

An important improvement as regards reciprocating engines was the fitting in 1899 of a system of forced lubrication to the main engines of the torpedo-boat destroyer Syren. The two engines of this vessel were each of 3100 indicated horse-power, and ran at 400 revolutions per minute. The application of this system was most successful, and it was extended to the engines of other torpedo-boat destroyers, and in 1904 to the engines of the battleships of the Britannia class, and subsequently to others.

Great benefits were thus obtained, including the practical elimination of the troubles of hot bearings. At this period the speeds had increased in our largest propelling engines to 140 revolutions per minute in some cases, although 120 revolutions was the general practice; but to go beyond this speed was considered to be running risks of obtaining engines which would not be satisfactory on service. With a good system of forced lubrication, however, this difficulty was largely removed, and higher speeds of revolution would have been possible, with a consequent decrease in the weights of machinery, had not the introduction of the turbine made this unnecessary.

An improvement which has added to the working efficiency of the reciprocating engine has resulted from our greater knowledge of the principles involved in the balancing of the external forces acting in marine engines, by which smoothness of working and reduction of vibration have been effected. The reciprocating engine has proved a most excellent servant, and will, without doubt, continue to do useful work for a considerable time. It is the development of large and extended experience, and has become a very efficient machine.

The most important development in the period under review is the introduction of the steam-turbine, and a paper of this nature would not be complete without reference to Sir Charles Parsons, whose engineering ability has brought the turbine to such a state of perfection as to allow of its successful use in practically all warships and in many ships of the mercantile marine. Recently Sir Charles Parsons has also shown how to obtain the advantage of the economy of high-revolution turbines by gearing them to suit the slower revolution of propellers both for the slower-speed vessels of the mercantile marine and for reducing the consumption at low powers in ships of war. As he is himself reading a paper on the subject of the development of the steam-turbine, it will not be necessary for me to refer at any length to this question. The introduction of the Parsons steam-turbine was accompanied by a lowering of the boiler pressure from that in use at the time with reciprocating engines, as the advantage to be gained in economy by the use of very high pressures did not appear to be commensurate with the increased weight involved, especially as in the turbine a more fruitful source of economy existed in the lowering of the back pressure.

A paper published in 1899 by one of our honorary members, the eminent French Director of Naval Construction, M. L. E. Bertin, stated. "It is easier to raise the initial pressure than to lower the back pressure; these are the two principal means of improving the economic conditions." This was the engineering view current at that period, and it is therefore worthy of note that ten years later we should find ourselves abandoning the easier plan of raising steam pressures, and making every effort to effect the more difficult task of lowering the back pressures to the economical limit, a task in which considerable success has been attained.

The great advantage of the steam-turbine is that it allows us to utilise conveniently, to a greater extent than previously, the energy existing in the steam at the lower limits of temperature, and this has caused the condenser and air-pump design to be very carefully investigated, with excellent results as regards vacuum obtained. It was not uncommon with the reciprocating engine to consider a high vacuum as a doubtful advantage, but this is now the subject of a guarantee in most machinery contracts for turbines.

The first war-vessel fitted with turbines was the Viper, and this vessel obtained the very high speed of 33.838 knots. This ship was followed by the Cobra, but, unfortunately, both were wrecked before any extended experience was obtained. The next important application was in the third-class cruiser Amethyst, which carried out her trials in 1904. To compare the results obtained from the turbines with those from reciprocating engines, the Topaze, a sister vessel, carried out an exactly similar series of trials, every effort being made to obtain the best results in each ship. These trials established the general superiority of the turbine as regards high-power working, and formed the basis on which our warship turbines have since been designed. Since the date of these trials, the fitting of the turbine has become almost universal in the British Fleet.

The Dreadnought was the first battleship fitted with turbines. She was followed by the armoured cruisers of the Invincible class (41,000 shaft horse-power), the trials of all of which were quite satisfactory. In the latter ships the water consumption at full power averaged 12 lb. per shaft horse-power for turbines alone, while at a speed corresponding to 10 knots—viz., 3500 shaft horse-power—the average consumption was 22 lb. per shaft horse-power. The consumption of turbine machinery at very low powers, although recently improved, is still comparatively high, but it is compensated for by efficiency and economy at high power, and other advantages possessed by turbine machinery. A very large number of torpedo-boat destroyers have been fitted with turbines, and with oil fuel for boilers the result is a very effective combination.

Most existing turbine ships of large size have four shafts, the two on each side having turbines in series; while the smaller installations have three shafts, the two high-pressure turbines in the wings exhausting to the low-pressure in the centre. Recently, however, two-shaft arrangements with combined impulse and reaction turbines of various types have been introduced, and some have been already satisfactorily tried, notably those in the cruiser Bristol and the destroyer Brisk.

Proceeding next to the important question of weight of machinery, Table I., page 20, shows the horse-power obtained per ton of machinery at various periods. The development in floor space is equally interesting, and for large ships the following table shows the space occupied in typical ships of various periods, the power taken being that developed on the eight hours' or other long trial:—

Floor Space Occupied by Engines and Boilers.

		Sq. Ft. per Horse-Power.
Warrior	1860	0.785
Bellerophon	1865	0.79
Devastation	1870	0.69
Shah	1875	0.64
Edinburgh	1880	0.64
Howe	1885	0.615
Royal Sovereign	1890	0.495
Prince George	1895	0.543
Canopus	1900	0.406
New Zealand	1905	0.38
Collingwood	1910	0.357

Reliability of machinery has much increased during the fifty years under review, and this is proved by the comparative immunity from breakdowns of H.M. ships. It is more particularly evident when the large amount of steaming now carried out, both on naval manœuvres and general service, is compared with the much smaller amount done by earlier ships. Considering the increase in piston speed and revolutions of later ships, this must be considered especially satisfactory. These increases are shown in the following table:—

Piston Speeds and Revolutions.

	Date.	Piston Speed. Ft. per Min.	Revs. per Min.
Warrior	1860	440	55
Sultan	1870	639	71.5
Inflexible	1880	616	77
Royal Sovereign ...	1890	900	105
Albemarle	1900	960	120
Lord Nelson	1910	1000	125

The gradual and considerable increase of power of ships of the Royal Navy, both individually and collectively, has been previously referred to. The collective increase is shown in the following table, giving the total horse-power of ships in the Navy List at the end of decennial periods:—

	Reciprocating Engine. I.H.-P.	Turbine. S.H.-P.
1860	541,175	—
1870	576,980	—
1880	814,200	—
1890	1,453,200	—
1900	2,985,400	10,000
1910	3,510,530	1,470,450

These increases of power and speed cannot, of course, be obtained without corresponding additions in the quantity of fuel consumed by the fleet. The very considerable increase in this item of maintenance is shown in the next table:—

Fuel Consumed by the Fleet.

	Coal. Tons.	Heavy Oil. Tons.	Petrol. Tons.
1860	100,000	—	—
1870	150,000	—	—
1880	200,000	—	
1890	400,000	—	—
1900	900,000	—	
1910	1,440,000	43,500	3,500

The initial cost of the machinery will also naturally be expected to have risen considerably with its increased weight and power. This feature of the last fifty years is shown in Table III., page 21, giving the cost of machinery of typical ships in each of the decennial periods.

In tracing the development of the warship's propelling engine during the period under review, many interesting matters of detail might be referred to, but it is only possible to do this in the briefest manner.

Methods of increasing the quantity of steam produced from a given weight of boilers have always been attractive to warship engineers. Warships in 1860 had no such methods other than the ordinary funnel.

In the Navy the steam blast (first fitted in the Monarch in 1869) was an effective method of increasing the draught, and continued to be common until about 1884, when it was finally abandoned. This method was very wasteful of steam, and also of fresh water, although at that period the necessity of maintaining the feed water as fresh as possible was not as important a feature in the working of the boilers as at present. The heavy loss of fresh water, unavoidable with the blast system, led to the introduction of fan-engines in the stokehold in 1870. These early fans, however, were more in the nature of ventilators, ensuring an ample supply of air, and it was not until 1880 that the closed stokehold system was first tried, and what has been termed "forced draught" introduced. The introduction of this method of increasing the rate of burning coal was attended with many difficulties, and the higher temperatures resulting revealed the weak parts of the boilers of that period. These difficulties were at one time so serious with the type of boiler fitted in many warships as to cause great anxiety, and it is not too much to say that for some years they constituted a serious menace to the war efficiency of the fleet.

The locomotive boilers, especially those which were first ordered in 1887 for torpedo gunboats, gave a considerable amount of trouble in the endeavours to obtain a large output of steam from a small weight of boiler. The great difficulty of keeping the tube ends in the combustion chamber tight, due to inadequate circulation over the whole plate, led even to the extreme measure of fitting centrifugal pumps in the boilers for the purpose of obtaining a sufficient and definite circulation. It is very interesting to read, in the light of present experience, the suggestions of the principal engineers of this country (including locomotive engineers) to overcome the difficulties then encountered. In those days brass tubes and copper fire-boxes were considered necessary in locomotive boilers to allow of the heat being readily conducted to the water. Troubles were, however, by no means confined to locomotive boilers.

A considerable number of experiments were made in the endeavour to overcome these difficulties, including very exhaustive ones with various types of ferrules fitted in the tube ends for preventing leakage, and the introduction of the Admiralty pattern cap ferrule did much to maintain the efficiency of the boilers under forced draught conditions at this period. Other systems of forcing the fires were also experimented with, but experience showed the closed stokehold system to be most suitable to warship requirements.

Important changes have taken place in the period under review as regards auxiliary engines, especially in their more extended application for various purposes.

Table IV., page 21, gives a list of the auxiliary machinery as fitted in modern war vessels and their approximate powers, and also the auxiliary machinery fitted in the most powerful vessel of 1860, from which the very great importance of the auxiliary-engine work of modern warships as compared with that of the early types will be evident.

The table shows the large amount of steam which must now be used for purposes other than the propulsion of the ship, and what a considerable quantity of heat is contained in the exhaust steam for those engines. The adoption of the well-known closed exhaust system a few years ago has had a beneficial effect in greatly reducing the fuel expenditure for such auxiliary purposes.

With the increase in the power of machinery and in the number and variety of auxiliary engines, a demand has arisen for greater facilities for dealing with repairs. In 1860 new ships carried no machine-tools, and depended for machine tool work, when not in dockyard hands, upon the floating workshop attached to each of the principal ports. At the present time every ship above the rating of a destroyer carries a good equipment of modern lathes and other machine-tools, together with other up-to-date appliances capable of dealing with all ordinary defects that arise. Repair ships, with very complete outfits, are attached to various squadrons for dealing with items of greater magnitude. In addition, modern ships contain appliances for the health, convenience, and comfort of the crew, which require steam or distilled water, and create a considerable further demand on the boilers.

An important change has gradually taken place in the manner of working the auxiliary engines which are necessary for the use of the main engines and boilers. These were at first practically all worked by rods or levers from the main engines themselves, but they have been removed one by one and worked by independent engines. Although it is not so economical as regards steam consumption to drive these auxiliaries by separate engines as to drive

them from the main engines, the great convenience of the former arrangement has been recognised.

Considerable difficulty was often experienced in satisfactorily feeding the boilers by the main feed pumps when they were driven off the main engines, and about 1875 separately-driven feed-pumps were introduced, and there was thus removed considerable anxiety as regards the certainty of the supply of feed water to the boilers.

In 1878 a further development was made in fitting separate circulating pumps of the centrifugal type in place about 1875 in connection with searchlights and subsequently with the internal lighting of ships. No one more than the marine engineer appreciates the comfort attached to electric lighting, and the great aid it is to him in carrying out his duties satisfactorily.

Like all innovations, difficulties were experienced in the initial stages with the generating machinery, and even at present they are not quite unknown. The increased use of electric-motors for various purposes on board warships may be recorded as one of the principal changes engines adapted for capstan duty in the Hercules in 1866, while in recent years electric motors have displaced the steam-engine for driving the capstans. The steering-engine remains on much the same lines as first designed, and was first fitted about 1866. Boat-hoisting engines were first fitted in the Ajax in 1881. These first engines were steam-driven. Electric and hydraulic systems have since displaced the steam-engines in new ships. Hydraulic pumping-engines for use in connection with gun-working machinery were also first fitted in the Ajax in 1881. Thee

of those which had hitherto been driven off the main engine. Separately-driven fire and bilge-engines were introduced in 1881. The main air-pump survived for some time as the last auxiliary engine driven off the main engines, and the replacement of this type by the separately-driven pump did not take place entirely until about 1902. Although the reciprocating pumps now fitted for these auxiliary purposes are very reliable, they are in their turn threatened with rivals in the shape of the turbo-pumps which are being perfected and used for various auxiliary purposes.

Electric generating engines were first fitted in ships which have taken place during the period under review. The engine first used for generating electricity was of the open type; then, about 1885, the Willans engine was generally used. A return was again made to the open type of engine about 1891, and about 1898 this was replaced in new ships by the enclosed forced lubricating-engine, which has been very successful. The turbo-generator has now made its appearance on board our ships; the great advantage of the turbine naturally commends itself.

There is not much to record in the development of capstan engines, except that the first so fitted were fire-engines are of the horizontal compound type, and have not changed much in design since those first fitted. Air-compressors for torpedo work were first adopted about 1880.

Steam boats were first carried by warships in 1869. The development in the engines and boilers of these boats has been on somewhat similar lines to that of the main propelling engines. Most of the present boats are fitted with water-tube boilers and two-cylinder forced-lubrication engines with surface condensers. A number of oil-motors have been tried, but these have not given entire satisfaction, although some are giving improved results. Superior types, however, to the ones at first

fitted are now being fitted, and the many paraffin and petrol motor-boats now being successfully introduced represent the tendency of development in this matter at the present time.

During the period under review the source of power has up till recently been coal, but within the last few years a powerful rival has appeared in the shape of liquid fuel. The inherent advantages of liquid fuel for the generation of steam in marine boilers, especially for warships, have been recognised for many years, but the practical difficulties which hindered its successful use for this purpose were not overcome till about 1904.

In the early experiments with liquid fuel the smoke which was given off was often very heavy, but now, where oil fuel only is burnt, as in some of our torpedo craft, the production of smoke is completely under control, except for a few minutes at lighting up, and even under these conditions very little need be made, while on ordinary running smoke can be prevented entirely, or readily kept down to such a minimum as will indicate the economy of combustion. Where both coal and oil are burnt the elimination of smoke is more difficult, but experience has shown that under these conditions the careful use of the modern appliances enables the smoke to be kept down to a lesser amount than with coal only, without interfering with the efficiency of the combustion.

Coming to progress in the use of oil as a source of power without the interposition of a boiler, internal-combustion oil-engines using heavy oil have been in use for many years in ships of the Royal Navy for driving dynamos; such engines are at present heavier than the actual steam reciprocating engines they replace, but if the boiler power, condenser, steam-pipes, &c., required to drive such reciprocating engines are taken into account, the difference in weight largely disappears. These oil-driven dynamos, for Service reasons, use oil of flash-point not less than 200 deg. Fahr., and the convenience which attends their use is considerable. This would be particularly the case in small ships which do not require to keep steam for drills, &c., and where motor-pumps for fire and similar purposes are available. Many initial difficulties were experienced in the working of these engines; the arrangement for the discharge of the exhaust gases was often inconvenient, and the fitting of oil-driven dynamos to later warships has been discontinued. These difficulties, however, have now been practically overcome with the further experience obtained, and recent reports respecting these engines are so satisfactory that their re-introduction will no doubt be considered.

TABLE II.—*Economy Due to Rise in Steam Pressure.*

Date.	Ship.	Load on Safety-Valves.	Horse-Power.	Coal per Hour per H.-P.
		lb. per sq. in.		
1848	Phœnix	6	400

1910	Neptune	235	27,721	1.46

* Trial after fitting with new boilers and engines.

The use of the internal-combustion engine for marine propulsion, during the period under review, does not provide much to record in the way of actual changes made, beyond the fact that these engines have been successfully installed in submarines and small craft. Little has been actually accomplished in warships. The large reduction in consumption of fuel obtained by the use of the oil-engine is, however, a great incentive to renewed effort to obtain satisfactory engines of large size, and the future is full of promise in this direction, and great changes may be anticipated in respect to the adoption of such engines for propulsion when the mechanical problems of their construction and of their reliability for continuous working have been satisfactorily solved.

No review of this kind would be complete without a few remarks respecting the officers and men who have charge of the machinery fitted in our warships, and the important changes which have taken place in their character and numbers.

The following table shows the great increase and corresponding importance of the engineering *personnel* which has taken place in the period under review:—

	Officers.	Men.
1860	1092	3,797
1870	1183	3,926
1880	795	5,056
1890	698	10,377
1900	970	24,805
1910	1461	37,221

To compare the total number employed in the engine-room department of a first-class ship in 1860 and 1910, we may take the Flag Ship of the Channel Squadron of 1860—viz., the Royal Albert, and the corresponding ship of the present day—viz., the Neptune, the present Flag Ship of the Home Fleet:—

	Horse-Power.	Engine-Room Complement. Officers.	Men.
1860. Royal Albert	500 N.H.-P.	7	20
1910. Neptune ...	25,000 S.H.-P.	7	224

The seven engineer officers in the Royal Albert consisted of:—

One chief engineer, two first assistants, two second assistants, and two third assistants, of whom only the chief engineer appeared in the Official Navy List. It was not until 1870 that junior engineer officers' names were inserted in the Navy List.

The twenty men of the Royal Albert consisted of five leading stokers and fifteen stokers, which staff had to be supplemented by hands from deck for coal-trimming when the ship was at sea under steam.

TABLE III.—COST OF MACHINERY.

Date.	Type of Vessel.	Name.	Total Weight of Machinery.	Cost.	H.-P.	Type of Engine.	Type of Boiler.	Load on Safety Valve.
			tons	£				lb. per sq. in.
1860	Armour plated broadside ship	Warrior	898	74,409	5,470	Horizontal, simple jet-condensing trunk	Rectangular	22
1870	Ditto	Sultan	1276	76,042	7,720	Horizontal trunk, surface-condensing.	Low pressure	30
1880	Battleship ..	Collingwood ..	1244	117,690	9,570	Vertical, compound	Elliptical	90
1880	Cruiser ..	Forth	568	50,000	5,700	,, ,,	Cylindrical	110

Total	94	6225	106	6331	8	350

* Not included in total.

The gradual reduction in comparative number of engineer officers compared with men will be evident from an examination of this table. In 1860 mechanics entered for the service of the engine-room obtained recognition as junior officers. Such procedure would, of course, now be impossible, owing to the large increase in the number of mechanics carried on a warship consequent on the great extension of mechanical appliances which has recently taken place, and, although the number of engineer-officers in modern warships is small, there has been no diminution in the amount of mechanical skill proportionately present.

In connection with the preceding table, showing the numbers of engineer-officers from 1860 to 1910, it may be noted that 1910 was the last year in which any engineer-officers, as they have hitherto been known, passed into His Majesty's Service.

In concluding this review, it may be remarked that, although much satisfactory progress has been made during these fifty years, many interesting and difficult engineering problems, the solution of which will mean further advance, remain for the coming generation. There is no finality; developments are continually taking place, and great efforts are being made every day to obtain higher efficiency. There is plenty of scope for the enthusiast, and there can be no doubt that this Institution will continue to be the means of bringing details of progress made, and the possible lines of further advance, to the notice of the marine engineering profession generally, and of aiding and encouraging the labours of those who are working in the important field of experimental research, and of the practical application of the results of such to the advancement of naval architecture.

APPENDIX.

Extract from Report of an Admiralty Committee (1858).

"From the experience thus gained, the Committee have no difficulty in coming to this conclusion, that, of all the variety of engines that have been purchased by Government for our screw ships of war, the following are so far superior to all others that no engines of an older make should ever again be put on board. The engines to which they now refer are:—

"1. The single piston-rod engine, with the connecting-rod attached direct to the crank-shaft, and with a single flat guide.

"2. The engine commonly known as the trunk engine, and patented by Messrs. Penn and Sons.

"3. The double piston-rod engine.

"There can be no doubt, as already stated, that these three forms of construction for engines are not only better suited for the navy than any other kinds that have been purchased for men-of-war, but also that they are better suited for those purposes than any modifications of the steam-engine that have as yet been constructed.

"But another and a further question arises, and that is the question, the relative merits of these three engines. On this point the Committee would say that, if any one be found to be superior to the rest, or should an engine be found, on future examination and experience, superior to all others, the Government ought to adopt that engine, either when they are purchasing new engines, or when making engines in their own factories, because the Committee would strongly urge that all engines furnished to our men-of-war should have all that modern knowledge of steam machinery can produce; nor do they see any reason why engines should ever be received into the naval service at all in which there is any degree of inferiority whatever to other engines which may be procured.

"Bearing these principles in mind, the Committee, after the most careful examination of the actual performances of various engines, and carefully weighing the evidence which has been given, have arrived at the conclusion that for very small engines the single piston-rod engine, as adapted by Messrs. Humphrys, Tennant, and Dyke, is the best engine suited for the Navy. Indeed, it seems now to be almost universally admitted that the single piston-rod engine is superior to all other known engines for very small power; and it may be noticed that for the later-built gunboats two of our most eminent engineering firms adopted that construction.

"The Committee are of opinion, with our present knowledge of steam machinery, that up to 300 collective nominal horse-power there is no engine for men-of-war superior to the single piston-rod engine, with a single flat guide; and they are not prepared to say that above that power its qualities may not be found equally good; and that the trunk engine, as constructed by Penn and Sons, has answered so extremely well, more particularly where great power is required, that the Committee recommend that, with such improvements in the details of these two engines as experience points out, they should be considered for the present the naval engine.

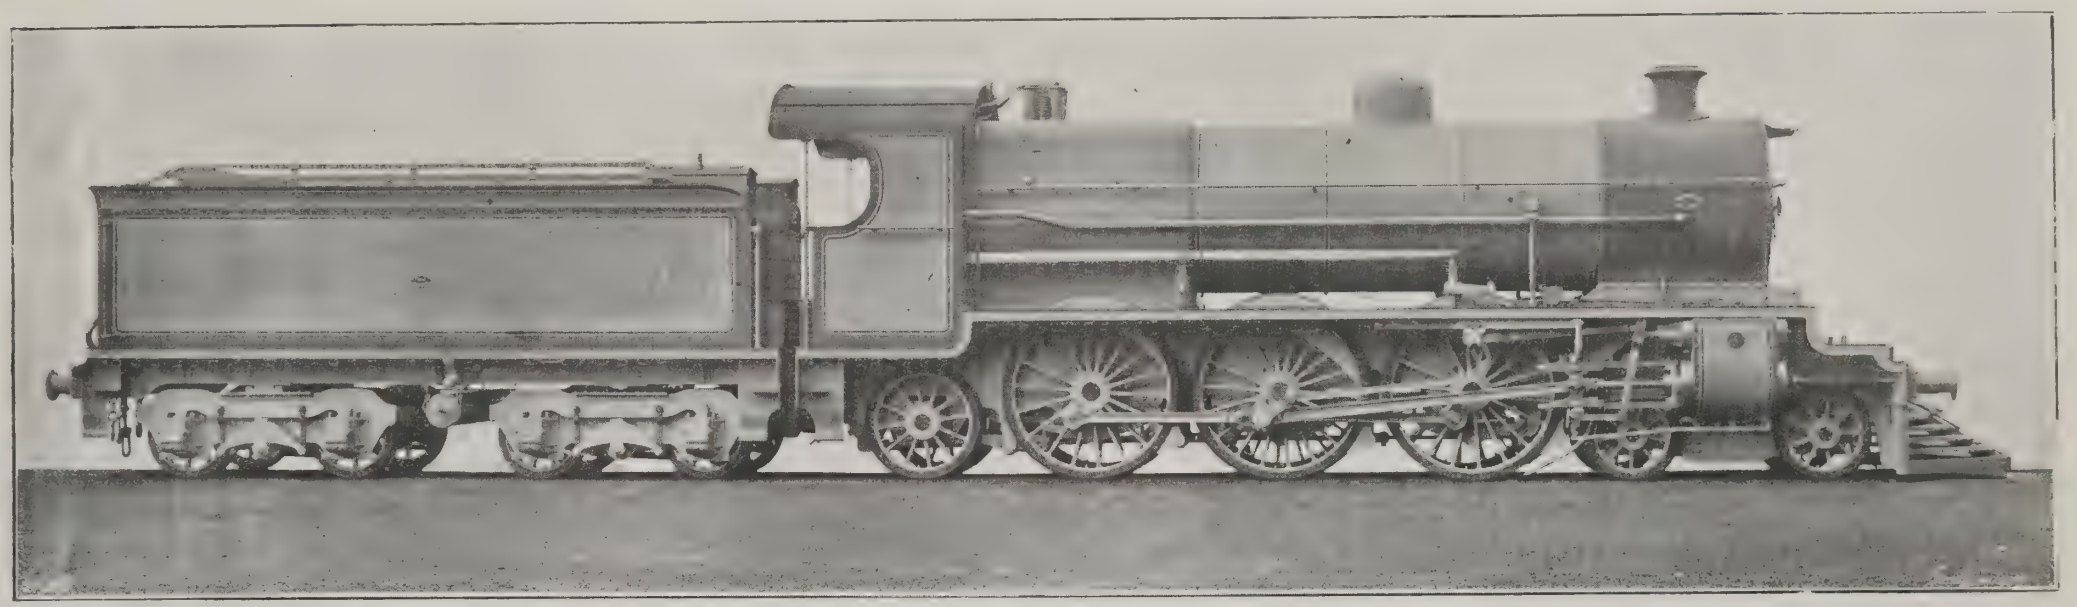
INSTITUTE OF MARINE ENGINEERS.—At the Royal Botanic Society Gardens on Friday, June 30, a reception and concert was held under the auspices of the Institute of Marine Engineers, when the High Commissioner for New Zealand, the Hon. Sir William Hall-Jones, K.C.M.G., made the presentation of the Gold Emblem of New Zealand, given by the marine engineers of New Zealand, to Mr. Frank Reddaway, J.P., of Manchester.

THE BRITISH MOTOR-BOAT CLUB.—This club will hold its annual London to Cowes race on Saturday, July 22. The race will start from Erith at 7.30 a.m., and will be for sea-going motor-yachts (according to M.M.A. definition) and estuary cruisers, fitted with internal-combustion engines, under M.M.A. rules, rating, and time scale. The course is from Erith to Cowes—176 nautical miles—and a silver cup, value 10*l.*, will be given for the first vessel completing the course.

VICKERS IRONCLAD CRANE PANELS.—A new design of crane panel is being introduced by the Electric and Ordnance Accessories Company, Limited, of Aston, Birmingham. Although these panels are of particularly substantial construction, both electrically and mechanically, they are considerably smaller and lighter than panels of the usual construction. The panels consist of a double-pole, quick-break main switch, with three or four double-pole branch fuses, enclosed in a cast-iron case, which is provided with lugs for fixing. The main fuses are mounted on the movable switch-arm, so that they can only be renewed when the switch is in the "off" position. Pilot lamps are mounted on the top of the case to indicate when the motors are entirely disconnected from the mains; connections for an inspection lamp are also provided. The panels are supplied to control one, three, or four motor circuits dealing with currents ranging from 50 to 400 amperes at pressures up to 600 volts.

PASSENGER LOCOMOTIVE FOR THE CENTRAL ARGENTINE RAILWAY.

CONSTRUCTED BY MESSRS. BEYER, PEACOCK, AND CO., LIMITED, GORTON, MANCHESTER.



THE illustration above represents an exceptionally heavy and powerful 4-6-2 type passenger engine, and is one of a number now being built by Messrs. Beyer, Peacock, and Co., Limited, Gorton, near Manchester, for the Central Argentine Railway, to the specification of Messrs. Livesey, Son, and Henderson, of London. The engine has outside cylinders and steam-chests, and is non-compound. The valves are of the piston type, and Walschaert's motion is employed. The boiler is of the Belpaire type, with steel shell plates, and is stayed with Stone's bronze stays. The tubes are of brass. The bogie at the front end is of the swing link pattern, and the trailing axle is mounted in a radial axle-box. The springs of the coupled and trailing axles are compensated in two groups, the compensating beams rocking on knife-edges instead of on pins, as is customary in British-built engines. The smoke-box is equipped with a Stone's "louvre" spark-arrester. There are four Ramsbottom safety-valves, each 3½ in. in diameter, and blowing off at 180 lb. pressure. Lubrication of the cylinders is effected by a Wakefield mechanical lubricator, actuated from one of the expansion links.

It will be seen that the tender is mounted on two bogies, which are of the compensating-beam type, and the brake-blocks are placed between the wheels. Both engine and tender are provided with steam-brakes working in conjunction with the automatic brake on the train.

The following are the leading particulars of the engine and tender:—

Gauge of rails	5 ft. 6 in.
Cylinders:	
Diameter	19 in.
Stroke	26 in.
Centre to centre	7 ft. 7 in.
Wheels:	
Diameter of bogie	3 ft. 2 in.
,, coupled	6 ft. 2½ in.
,, bogie	4 ft. 1 in.
	Radial axle-box.

Wheel-Base:	
Centre of bogie to front drivers	8 ft. 8¾ in.
Front to middle drivers... ...	6 ft. 7⅝ in.
Middle to hind drivers	6 ft. 7⅛ in.
Hind drivers to trailing axle ...	6 ft.
Bogie wheel-base	6 ft. 6 in.
Extreme wheel-base	31 ft. 3½ in.
Boiler:	
Length	14 ft. 4¾ in. Telescopic
Diameter outside at front ...	5 ft. 6¼ in.
Height of centre from rail ...	9 ft. 7¾ in.
Tubes:	
Number	257
Diameter	2 in.
Length between tube-plates .	14 ft. 10½ in.
Copper Fire-Box:	
Length inside	7 ft. 11¾ in.
Width inside	3 ft. 8⅝ in.
Height at front inside... ...	6 ft. 9½ in.
Height at back inside	5 ft. 5½ in.
Centre of boiler to roof inside ...	9½ in.
Fire-Box Casing:	
Length outside	8 ft. 8 in.
Width outside	4 ft. 4¾ in.
Centre of boiler to top of shell...	3 ft. 0$^{3}_{16}$ in.
Shape of top and how stayed ...	Belpaire
Heating Surface:	
Tubes	2001.5 sq. ft.
Fire-box	166 ,,
Total	2167.5 ,,
Area of fire-grate	29.5 ,,
Boiler pressure	180 lb. per sq. in.
Tractive power per pound of mean effective pressure in cylinder	126

Weight on Rails in Working Order:	Tns.	Cwt.	Qr.
Bogie-wheels	18	5	1
Front driving-wheels	15	7	0
Middle driving-wheels	15	10	1
Hind driving-wheels	15	3	3
Trailing wheels	12	16	2
Total	77	2	3

Tender:	
Water capacity	6000 gals.
Fuel capacity	260 cub. ft.
Wheels, diameter...	3 ft. 2 in.
Wheel-base...	Centre to centre of bogies, 13 ft.; centre to centre of bogie wheels, 6 ft.
Shape of tank	Sloping
Brake	Steam and hand-screw

Weight on Rails; Full:	Tns.	Cwt.	Qr.
Front bogie	29	0	0
Hind bogie	29	18	0
Total	58	18	0

NOTES FROM THE SOUTH-WEST.

Cardiff.—Labour troubles have restricted business, buyers and sellers preferring to hold their hands for the moment. The best large steam coal has made 18s. 6d. to 19s. per ton; secondary qualities have ranged between 16s. and 17s. 9d.; best ordinary bunker smalls between 10s. 3d. and 10s. 6d., and cargo smalls between 9s. to 9s. 3d. per ton. House coal has shown scarcely any change; the best ordinary qualities have made 14s. 6d. to 16s. 6d. per ton; No. 3 Rhondda large has brought 17s. to 17s. 6d. per ton, and smalls have made 10s. 6d. to 10s. 9d. per ton. No. 2 Rhondda large has been quoted at 11s. 9d. to 12s. 3d., and smalls 8s. to 8s. 6d. per ton. Foundry coke has realised 18s. to 20s. 6d., and furnace ditto, 16s. to 17s. per ton. As regards iron ore, Rubio has been quoted at 18s. 6d. to 19s. 6d. per ton, upon a basis of 50 per cent. of iron, and charges, including freight, insurance, &c., to Cardiff or Newport.

Death of Mr. I. T. Rees.—The death is announced of Mr. Ithel Treharne Rees, a mining and civil engineer and a member of the firm of Forster Brown and Rees, of Cardiff and Westminster. The deceased formerly lived at Penarth, but latterly he resided at Blaen-y-Pant, Malpas, Newport. He was born at Bassaleg, Monmouthshire, in August, 1852. He was articled to Messrs. Dobson, Brown, and Adams, of Cardiff. He was in charge of the sinking of Harris's Deep Navigation Colliery at Treharris, and afterwards joined Mr. Forster Brown as a partner. From 1879 to 1882 he held the position of Inspector of Mines for Glamorgan, acting under the late Mr. T. E. Wales. He was at his death president of the South Wales Institute of Engineers. He was also a member of the Institution of Civil Engineers and of the Surveyors' Institute.

Dowlais.—The works have been fairly active. The Goat Mill has been engaged on an Indian order for heavy steel rails, tin bar, &c. The Big Mill has been working on angles, flats, fish-plates, &c. The quantity of coal raised has been larger than usual.

Bristol University Degrees.—The Council of the Institution of Civil Engineers has decided to accept the degree of the University of Bristol in civil and mechanical engineering (awarded under new regulations) as exempting from an Institution examination for associate membership. Bristol degrees will also be recognised by the India Office as qualifications for appointments as assistant engineers in the Public Works Department of India.

CANADIAN PACIFIC RAILWAY.—The extensions and improvements proposed to be undertaken by the Canadian Pacific Railway Company this year will represent an outlay of about 6,000,000*l.* The extensions include a line to the Brazan coal-mines in Alberta, a line from Athabasca Landing to North Battleford, and another from Edmonton to Fort Mann.

THE ROYAL INSTITUTE OF PUBLIC HEALTH.—On August 15 next the Royal Institute of Public Health will hold its annual congress in Dublin for the third time. The first congress was held there in 1892. The meetings will take place at Trinity College, the University Board having kindly placed the halls at the disposal of the congress committee. The congress will be under the presidency of Her Excellency the Countess of Aberdeen, herself well known as an earnest and indefatigable worker in the cause of public health.

AGENTS FOR "ENGINEERING."

AUSTRALIA: Gordon and Gotch, Melbourne; Sydney; Brisbane; Perth.
Turner and Henderson, Sydney, N.S.W.
T. Willmett and Co., Townsville, North Queensland.
W. C. Rigby, Adelaide, South Australia.

INDIA, Calcutta: Thacker, Spink, and Co.
Bombay: Thacker and Co., Limited.
ITALY: U. Hoepli, Milan, and any post-office.
LIVERPOOL: Mrs. Taylor, Landing Stages.
MANCHESTER: John Heywood, 143, Deansgate.
NEW ZEALAND: Gordon and Gotch Proprietary, Limited, Wellington, Auckland, and Christchurch.
NORWAY, Christiana: Cammermeyer's Boghandel, Carl Johans Gade, 41 and 43.
ROTTERDAM: H. A. Kramer and Son.
SOUTH AFRICA: Central News Agency, Limited, Head Office—Johannesburg; and Pretoria, Cape Town, Port Elizabeth, Bloemfontain, Durban, and their various branches and bookstalls throughout South Africa. Also Cape Town: Wm. Dawson and Sons, 31, Long-street.
SWITZERLAND: **Sole Agents for Advertisements:** The Dean-Mayer Company, Linkstrasse 39, Berlin, W. 9, Germany.
TASMANIA: Gordon and Gotch Proprietary, Limited, Launceston; Hobart.
UNITED STATES, New York: W. H. Wiley, 43, East 19th-street.
Chicago: H. V. Holmes, 957-968, Monadnock Block.
Sole Agents for Advertisements:—The Wm. S. Parry Co., 315, Dearborn-street, Chicago, and 366, Fifth-avenue, New York, U.S.A.

ADVERTISEMENT RATES.

The charge for advertisements is three shillings for the first four lines or under, and eightpence for each additional line. The line averages seven words. Payment must accompany all orders for single advertisements, otherwise their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper and on the inside pages may be obtained on application. The pages are 12 in. deep and 9 in. wide, divisible into four columns of 2¼ in. in width. Serial advertisements will be inserted with all practicable regularity, but absolute regularity cannot be guaranteed.

Advertisements intended for insertion in the current week's issue must be delivered not later than 5 p.m. on Thursday. In consequence of the necessity for going to press early with a portion of the edition, alterations for standing advertisements should be received not later than 1 p.m. on Tuesday in each week.

SUBSCRIPTIONS, HOME AND FOREIGN.

"ENGINEERING" can be supplied direct from the Publisher post free, for twelve months, at the following rates, payable in advance:—

For the United Kingdom	£1	9	2
For Canada—			
Thin paper copies	£1	11	6 ($7.65)
Thick ,,	£1	16	0 ($8.75)
For all other places abroad—			
Thin paper copies	£1	16	0
Thick ,,	£2	0	6

When foreign subscriptions are sent by Post-Office Orders, advice should be sent to the Publisher.

All accounts are payable to "ENGINEERING," LIMITED. Cheques should be crossed "Union of London and Smith's Bank, Limited, Charing Cross Branch." Post-Office Orders should be made payable at Bedford-street, Strand, W.C.

Offices for Publication and Advertisements, 35 and 36, Bedford-street, Strand, London, W.C.

With One Two-Page Plate and Four One-Page Plates of the DUNSTON POWER-STATION OF THE NEWCASTLE-ON-TYNE ELECTRIC SUPPLY COMPANY.

ENGINEERING.

FRIDAY, JULY 7, 1911.

ENGINEERING TRAINING AND ACHIEVEMENT.

THERE is appropriateness in the Conference of the Institution of Civil Engineers on the Education and Training of Engineers, held last week, being followed so closely by the International Congress of the Institution of Naval Architects. In the one case we had a full expression by many authorities of the requirements to be met by the engineer in the future; in the other, a comprehensive review of the work achieved by the engineers of the past, since the great majority of the papers read at the Congress were of an historical character. With this record of practical work done there is every reason to be satisfied, particularly in the case of Britain, and there is some assurance that thus far we have not suffered from any lack of appreciation of the need of sound training in order to ensure progress. At the Congress, too, convincing testimony has been offered by foreign delegates that our naval architects and engineers have assisted in promoting the training of their *confrères* of other nationalities. The progress made abroad has in the past been more or less evolutionary, although in recent years it has developed on more original lines. These later advancements in theory in foreign lands, the realisation of high efficiency, and the increase in the volume of work done, undoubtedly afford a strong incentive to all interested in our national industries to exert themselves still more in the direction of intense effort, in greater attention to the training of the younger members of the profession, and in the application in factories of a higher scientific knowledge. Thus, while the International Congress of the Naval Architects affords much satisfaction so far as the past is concerned, it incidentally justifies the Conference on the Training of Engineers from the point of view of the future.

The Conference must be pronounced a success, as it resulted in a thorough exchange of opinion on the fundamental principles of education, and no one can read the fairly full reports in our issues of last week and of this week without profit. Few will fail to be impressed with the importance as well as with the difficulties of the subject. Disappointment, however, will be experienced in many quarters from the fact that no attempt was made to crystallise opinion and to formulate general principles for the guidance of teachers, employers, and parents. We admit that the idiosyncracies of the students must influence the course of training in nearly every case, and that therefore a great latitude must be permitted in arranging the course. But the question arises whether guidance within wide limits would not have been of incalculable benefit. One must not forget, however, that in 1906 a committee of the Institution of Civil Engineers, under the chairmanship of Sir William White, investigated the whole question, and laid down recommendations in respect, firstly, of the preparatory education, and, secondly, of the advanced engineering training. These recommendations have been generally accepted as sound, but it would have been well to have utilised the opportunity afforded by the Conference to secure definite information as to how far these recommendations had been carried out, and how suitable they had proved, alike as regards the student, the college, and the factory. As Professor Barr pointed out, it was difficult to distinguish between the subjects dealt with at the different sections of the Conference, and it seems to us that, if it had been at all possible, it would have been more conducive to definite results if the subjects had been arranged so as to afford a consensus of opinion upon important questions of detail, which at present give rise to conflicting opinions.

There is first the vexed problem as to whether and how far practical training should be interposed between attendance at the secondary school and at the technical college. The recommendation of the Committee in 1906 was distinctly in favour of practical training being so interposed, and it is remarkable that 93 per cent. of those from whom opinions were then invited by the Committee were in favour of this proposal. In a recent article on the subject of the proposed bursaries by the Royal Commission for the allocation of the funds derived from the 1851 Exhibition (see page 693 of our last volume), we entered at considerable length into this question, and we are glad that the great majority of those who spoke at the Conference agreed with our view that practical work should precede theoretical study at the universities. There was, naturally, some difference of opinion as to the length of this practical course. The Committee already referred to recommended at least a year, and with this decision 72 per cent. of the opinions forwarded to the Committee agreed, while 21 per cent. thought a year insufficient. But the Committee, it will be remembered, was disposed to consider that two years, and even more, was the correct period for those who proposed to take up some branch of mechanical engineering. Employers should now, however, be satisfied with an expression of opinion in favour of this preference for factory work, leaving the time to be determined by each firm to suit the particular branch of engineering in which they are producers.

One gratifying feature of last week's Conference was the great importance attached by almost all the speakers, except the purely academical professors, to practical training. Some of the speakers raised the objection that the youth who had served one or two years before going to college experienced difficulty in again joining the ranks of practical workers at the end of his college course. This objection may hold in some cases, but in other instances arrangements are made whereby the youth returns to the same works. Messrs. Vickers, Limited, and other firms have almost ideal conditions, granting to apprentices who have shown themselves worthy of it the privilege of proceeding to college for two or three years after spending three years in the works, the whole period so spent at college to count as apprenticeship time, provided that the apprentice, in his periodical reports to the firm, discloses convincing proof that he is profiting by the special privileges granted. At the conclusion of the college course the pupil is bound to return to the same works, and the employer binds himself to take the student into his service, paying him a wage. The minimum payment is within the limits of a living wage; but it may be very much higher, according to the capability of the youth. This raises the question as to whether or not a degree or other evidence of college achievement is of commercial value. It is necessary to guard against the assumption that the possession of a degree is a guarantee that its holder is fitted for the charge or performance of responsible work; but, as the Chairman of Section II. (Scientific Training) pointed out on Thursday last week:—"If the work through which the student has gone to attain his degree is sound, it should serve him in good stead in his practical career, and he might fairly be expected to advance more rapidly than one who had not had similar training. If this result does not follow, then something is certainly wrong, and the sooner the reason is known the better." The idea seems to be held in some quarters that our manufacturing engineers have an actual objection to engineering degrees, but this idea is certainly unfounded—at all events as far as it relates to firms of high standing. The real state of the case, we consider, is this:—A young engineer of, say, twenty-three or twenty-four years of age will probably have had some six or seven years' training in college and workshop, and when such a man applies for an engagement the employer naturally considers how this time has been spent. If a good proportion has been devoted to gaining practical experience, and if, in addition, the applicant has secured a degree, then this degree is decidedly an asset of value. But if the degree has only been secured by the neglect of essential points of practical training, with the result that the applicant, though strong in theory, is weak in that knowledge of materials and of men which is so valuable in practice, then the applicant is likely to have to stand aside and give place to someone more calculated to be of real service to his employers.

The recommendation for the interposition of a practical course between the school and the technical college study may, as we have stated, be accepted as one general conclusion of the Conference, and it would have been well if such a conclusion had been embodied definitely in a resolution. The sandwich system possibly offers advantages in some cases, but the difficulty is to secure continuity either in practical or theoretical work. Six-month periods, alternating between college and factory,

are too short, apart altogether from the question as to how far they are permissible, without interfering with the aim of economic production.

There were some taking part in the Conference who held the view that frequent changes were disconcerting to the youth, and that the student looked upon the period in the workshop as a form of holiday, the general consensus of opinion seeming to be in favour of a complete course of three consecutive years being taken at the college, preceded by a period of practical training and succeeded by a further period in the factory. The recommendation has been made that in the final year at college, when the student was more or less specialising, he should seek a college in the district where his specialised work prevailed. In such case, for instance, the prospective marine engineer would go to Glasgow, and the textile engineer to Manchester, or Leeds, and so on, in order that the student might come into immediate and continuous contact with work in progess in the factory and with students and men who had been reared in the atmosphere of the industry. The difficulty, however, at present is that there is no attempt to standardise the curricula of technical colleges, and it would in many cases be impracticable to maintain satisfactory and complete continuity of study were the student passed from one college to another between the second and third years.

The course outlined at the Conference, while definite enough, loses sight of one important factor —that it ensures higher education only for the moneyed classes. Those who have followed the progress of all industries, and none more so than those of naval architecture and marine engineering, so completely reviewed in the historical papers read at this week's Congress of the Institution of Naval Architects, must recognise that much of the epoch-making work has been the product of men who have risen from the ranks. It was Lord Rosebery who brought convincing testimony from the world's records to prove that genius was discovered in poor more often than in wealthy circumstances. And this is true also in the case of that substitute for genius—the faculty of taking infinite pains. It were well, therefore, that the promising youth, whatever his social rank or financial resource, should be able to take full advantage of the best conditions. It was for this reason that we advocated that the Exhibition Bursaries, to which we have already referred, should be available for lads of humble circumstances worthy of special post-scholastic training at the works, college, and finally in the same works.

The Royal Corps of Naval Constructors, of which we heard so much at the Naval Architects' Congress, offers a good example alike in the course of training and in the stimulating results attained. The great progress achieved, as narrated in the papers on naval architecture, by Sir Philip Watts; on naval engineering, by Sir Henry Oram; on turbines, by Sir Charles Parsons; and on artillery, by Sir Andrew Noble; as well as in others, are most creditable; but it is no disparagement of the achievements of past workers to say that the future advances will call for higher scientific and practical abilities on the part of those who lead in industry. This is due to the difficulty of accomplishing successive improvements. There is also the evidence of keener competition indicated by the papers from some of our foreign friends. Their efforts are welcome from the standpoint of the advance of science, but must, as we have pointed out, awaken rivalry of the keenest kind, however friendly, if our commercial position is to be maintained. As with the marine industries, so with others, and thus it is incumbent upon the Institution of Civil Engineers and the kindred scientific associations to do all that is possible to aid in formulating guiding principles for the realisation of the highest efficiency in the principal of our national assets—the brain-power latent in youth.

THE NAVY ESTIMATES IN PARLIAMENT.

THE House of Commons passed the vote for shipbuilding on Wednesday after a somewhat desultory, and therfore unsatisfactory, debate. Under ordinary circumstances, one might assume that the absence of criticism on well-defined lines prognosticates confidence in the Government's policy towards the Navy; but the explanation is to be found rather in the prevalent state of lassitude in political matters generally, except, perhaps, those appertaining to the Constitutional question. This is unfortunate, because criticism is so essential in the maintenance of efficiency in the administrative departments, and in none more than at the Admiralty. The recent display of the preparedness of the Navy at the Coronation Review, and the progress of the battle exercises of the Fleet which followed, are no doubt reasons for satisfaction with the main question of the ability of the Fleet in commission to maintain our naval prestige. But there is at the same time, throughout the country, an undercurrent of suspicion that the financial consideration is weighing too strongly in the attitude of the Government in reference to the future. The Declaration of London has brought home the great need for a larger fleet of cruisers, and also for a closer union between the Royal and the Merchant Navies. This point was raised by Lord Charles Beresford, who has abundantly justified his ability as a critic within the House; and there will be a general consensus of opinion in favour of the plea put forward that the Admiralty ought to make preparation for utilising, to a greater extent, a number of fast ships in the merchant service for duty in the event of our food supply being menaced in war. This point, it will be remembered, has been frequently raised by Lord Brassey, who strongly favours perfect understanding between the Government and the owners of fast liners and fast Channel steamers, which latter, especially for scouting duty, might be of great use.

The First Lord of the Admiralty, in replying to the debate, urged that we were building suitable scouting cruisers in increased numbers, and gave promise, too, that next year more cruisers still would be provided; but he sheltered himself behind the need for secrecy, and refused to give any satisfying details regarding the proposals of the Admiralty for the defence of our trade routes. We are glad to note that such a high authority on Admiralty procedure, and on all questions affecting the maintenance of official secrets, as Sir William White should, on the same day as the debate in the House, have urged that there was a middle course in this matter, and that good must accrue from an intelligent discussion of Admiralty policy in the light of official information. It is true that his remarks applied more, perhaps, to details of construction and design, but the force of the argument is as great from the point of view of strategic and tactical questions. There is, of course, information which it would be suicidal to disclose, but many feel that in recent years the Admiralty have carried this refusal to take the public into their confidence to an unjustifiable length. Such experienced men of affairs as Mr. Balfour, Lord Charles Beresford, and Mr. Arthur Lee, have no desire to force the hands of the Government to an extent which would jeopardise our position in the event of war by the disclosure of essential facts, and they, like the great majority of citizens anxious to have confidence in the Admiralty administration, would be satisfied with a limited amount of information which would show that the Admiralty had grappled with the problem on broad and efficient lines.

There was, perhaps, less tendency to measure strength at future dates than in previous debates, but Mr. Balfour, in temperate language, impressed the Government with the importance of making such arrangements now as would enable the Navy to be prepared for any contingency at any date, and notably in 1914. These arrangements he was anxious to have applicable not only to battleships, but to the lighter craft essential to combating the anticipated conversion, even at sea, of foreign merchant ships into commerce-destroying cruisers under the new conditions created by the Declaration of London. Mr. Balfour also raised the question as to whether we were right in continuing to be satisfied with no gun between those of 13.5 in. or 12 in. calibre and the 4 in. bore. It is always difficult to hold the hand when one finds contemporaries taking a definite course, and there are many who are somewhat anxious as to whether the 4-in. gun will meet all the demands, when we find practically every Power adopting a gun of 6 in. or even greater calibre as secondary armament in battleships, in addition to 12 in. and 14 in. guns. Of course, the British Admiralty have gone on the assumption, based on logical grounds, that such guns are only for use in repelling torpedo attack, and consequently they refused to recognise the need for even secondary armament. Mr. McKenna, in replying to Mr. Balfour's contention for a complete consideration of this question, said that the problem depended on the type of the destroyer and the range of the torpedo. He admitted that the development of the torpedo in the last few years had been very remarkable, and stated that the Admiralty were considering the question with a perfectly open mind. The 4-in. gun was sufficient for a range up to 6000 or 7000 yards, but it might be that this was insufficient, and that a larger gun would require to be installed, so as to defeat the destroyer before the latter could get within range with its torpedoes.

THE JUBILEE MEETING OF THE INSTITUTION OF NAVAL ARCHITECTS.

ON January 16, 1860, eighteen British shipbuilders met, and constituted themselves "the Institution of Naval Architects, for the purpose of advancing the science and art of naval architecture." The constitution, objects aimed at, and qualifications for membership were prepared with marvellous prescience, with the result that the organisation has since grown in membership, in prestige, and in the wealth of influence continuously exerted towards the advancement of the science of naval construction in every department. This week a gathering of shipbuilders and engineers, representative of every nationality, is celebrating the jubilee of this organisation—a celebration which had, unfortunately, to be postponed last year, owing to the lamented death of King Edward VII., for many years the Patron of the Institution. All foreign technical societies and the most important British institutions have sent representatives, not only to rejoice with the members of the Institution of Naval Architects, but to pay homage to those who have done so much pioneer and successful work. Unfortunately, the limits of space available prevent our naming all of these representatives. We can only mention the principal of the delegations appointed by important societies:—The Académie des Sciences of France, Prince Roland Bonaparte; the Association Technique Maritime, Mons. L. E. Bertin, the *doyen* of the naval architects of France; the Schiffbautechnische Gesellschaft, the Geheimer Regierungsrat, C. Busley; the Verein Deutscher Ingenieure, Dr. Sorge; the Institution of Civil Engineers of Holland, Mr. A. van Gelder; the Collegio degli Ingegneri Navali e Meccanici, Signor Salvatore Orlando; the Japanese Society of Naval Architects, Constructor-Rear-Admiral Matsuo; the Swedish Institution of Naval Architects, Mr. A. Isakson; and the Society of Naval Architects and Marine Engineers of the United States, Mr. Stevenson Taylor. The Ministers of Marine of practically every country are represented by staff members of the Embassies resident in London, or by special delegates sent to this country to attend the Congress.

Meetings for the reading and discussion of papers were held in the mornings of Tuesday, Wednesday, and yesterday, and will be continued to-day, while the afternoons and evenings have been devoted to social functions, which are as influential in their effect on the advancement of the general aim. This point was enforced in several speeches made during the progress of the Congress, because, apart from the great advantage of the friendships thus formed, important problems are privately considered, perhaps with more direct interchange of personal knowledge than is sometimes possible publicly in these days of keen international competition and naval rivalry. Each of the functions will be noticed in due order in the course of our report, and it may be said at once that all proved most successful, a result consequent upon the admirable arrangements made by the Executive Council of the Institution, and by the Secretary, Mr. R. W. Dana, and furthered so willingly by the efforts of the Reception Committee and particularly of the stewards, who were most businesslike in their interpretation of the duties of their office.

The Congress opened on Monday evening with a reception by the President, the Most Honourable the Marquis of Bristol, Rear-Admiral, R.N., and the Marchioness of Bristol, at the Museum of the Royal United Service Institution, Whitehall. No more appropriate venue could have been chosen, because the members gathered in a naval atmosphere and amidst the replica of the achievements of the British warship designers of all ages, while those revered proofs of British prowess, with which the museum abounds, have—thanks to modern *ententes cordiales*—ceased to give rise to

unpleasant reflections on the part of our foreign visitors. The music too, provided by the Chapel Royal Choir, was appropriate to the occasion, so that the preliminary social gathering was in every respect a pronounced success.

The Inaugural Meeting.

The more serious business of the Congress was opened by a largely attended meeting of members and delegates from all countries, held in the Connaught Rooms, Great Queen-street, on Tuesday morning, when H.R.H. the Duke of Connaught, K.G., took the chair as Hon. President of the Congress. He was supported by the President, the Marquis of Bristol, by a Past-President, Lord Brassey, and by the leading foreign delegates. The postponement of the Congress from last year had one regrettable result. His Majesty King George V. had kindly promised to occupy the chair as Prince of Wales; and there was peculiar appropriateness in this, since he has had a life-long connection with the Navy and marine construction, and is, moreover, a patron of the Institution. His interest, all are glad to know, is still maintained, although be has succeeded to the more onerous and responsible duties of kingship.

The Duke, in opening the proceedings, said:

It is my pleasing duty, as your honorary president, to welcome all those who have come to attend the Jubilee meeting of the Institution of Naval Architects. As you are aware, this meeting was to have been held last year but for the sad calamity which then occurred, and on that occasion my nephew, our present King (then Prince of Wales), was to have presided. That meeting was obliged to be put off, but I am happy to think that we have been able to meet in this, the Coronation year of our present King. You will naturally feel that, as a keen sailor, his Majesty is in deep sympathy with the objects of our meeting, and he has charged me to express to you all his best wishes and his hope that the result of this year's congress may be of very lasting benefit, and that those whom we have the honour of seeing amongst us from foreign countries may enjoy their visit to England. I regret that as honorary president you have not a member of my family who is better acquainted with the great and important details of naval architecture, and that I appear before you as a mere amateur; but I assure you that, however little I may know of these important subjects, no one more appreciates the enormous advance that has taken place in naval architecture since you last met here in international congress in the Diamond Jubilee year of her late Majesty Queen Victoria, when my late brother was in the chair and addressed you. We have merely to look at the great ships now sailing on the waters to see the enormous advance that has been made during the last fourteen years. Advances of this kind cannot be made without consummate skill, consummate knowledge, and great application. I am sure that we in England appreciate the rivalry, the friendly rivalry, that exists in shipbuilding at the present time, and that we appreciate the fact that many great brains are at work to produce the wonderful results that we see before us at the present day. Those of us who had the pleasure of attending his Majesty's Naval Review at Spithead the other day could not help comparing the ships at this Coronation Review with those of only nine years ago; and when we consider in how short a space of time naval architecture has revolutionised itself we must recognise that the advance made is something colossal. Our newest battleship—I am open to correction—is the Neptune. We all saw her at Spithead, and thought how magnificent a ship she was; and our newest great Atlantic liner is the Olympic. We do not know where finality in size is going to end, and we certainly must recognise the wonderful combination of skill, knowledge, and mathematical work that can produce the wonderful ships of the present day. I suppose that, as in everything else, there is no finality, and that ships we may approve of and consider the best in the present day we may, perhaps, regard as old and rather interesting relics of the past when we meet again. I desire again to welcome you most warmly, and to assure you that it affords us the greatest pleasure to see you here to-day, and to enable you to see for yourselves what advances we are making in England.

At the conclusion of His Royal Highness's address, Rear-Admiral C. J. Briggs, Controller of the Navy, on behalf of the First Lord of the Admiralty, extended a welcome to the foreign members, and gave expression to the Admiralty's appreciation of the work done by the Institution. He referred to the high place that the officers of the Admiralty held in the organisation, and to the honours bestowed by the Institution also upon many executive officers of the Fleet. The Right Hon. Sydney Buxton, M.P., President of the Board of Trade, had intended to be present to similarly welcome the guests on behalf of the commercial department of the Government, but the Secretary, Mr. Dana, read a letter intimating his apologies and his great regret that a Cabinet meeting precluded him from attending.

The President, the Marquis of Bristol, then delivered the presidential address, which is reprinted in full on page 12 of this issue. Incidentally, the noble Marquis gave expression to the general sentiment of satisfaction that all present experienced at the earldom conferred upon Lord Brassey, a past-president of the Institution.

The History of the Institution of Naval Architects.

Sir William White, who has done yeoman service, not only for the Institution, but for the advancement of its aims and for the development of scientific shipbuilding generally, most appropriately read the first paper, which reviewed the history of the Institution and the progress of scientific education in naval architecture. This admirable *résumé* brought into strong relief the salient features of the Institution, and the continuous association of the organisation with the successive developments in shipbuilding, naval and mercantile. The first part of this paper is published in this week's issue (page 13), and the concluding part, which deals with the work of the Institution, will be published in next week's number. In this latter part Sir William referred to epoch-making communications to the Institution, and to the value of the keen discussions which had taken place on all subjects, notably on the constructive policy of the Admiralty for the time being. These controversies have been valuable in crystallising opinion, while the independent criticisms of Admiralty action has had a beneficial effect upon the policy pursued in respect both of broad principles and of details of design. There was quick appreciation and approbation by the great audience of Sir William's view as to the unfortunate changes which have recently taken place, under which no official communications have lately been made to the Institution respecting the designs of new British warships. He expressed the hope that before long there might be a reversion to the earlier and well-approved practice. It was not suggested that in future there should be disclosures of any information that would be indiscreet or improper, any more than there has been in the past. "As one familiar," Sir William said, "with the events of the last 45 years in our proceedings, I cannot recall one occasion where the public interests have suffered in consequence of the papers read and discussed, in which warship design and construction formed the subject."

Sir Nathaniel Barnaby was called upon by the President, and the greeting he received was enthusiastic, as he is the only survivor of the eighteen who were present at the constitution of the Institution fifty-one years ago. Sir Nathaniel, notwithstanding his great age, was heard in every part of the large hall in the few words of greeting which he gave, and was particularly happy in recalling the fact that the International Congress was being held on July 4, the great national holiday of our kinsmen in the United States of America.

Lord Brassey spoke next, and paid a well-merited tribute to Sir William White, referring to his work for the Institution, and particularly for the advancement of the profession of naval architecture. Since proficiency is aimed at, it was important, said his lordship, that the members of the profession should have dignity and honour bestowed upon them, and in this respect he referred to the work Sir William had done in bringing about the institution of the Royal Corps of Constructors at the Admiralty, and to his other efforts in connection with the Institution of Naval Architects.

Tributes by Foreign Delegates.

Several of the foreign delegates paid tributes to the Institution. Letters had been received from Dr. Schlick, Signor Soliani, and Sir George Holmes. M. Bertin was the first to speak, and was followed by Mr. Taylor, of the American Society; Dr. Sorge, a member of the Council of the Verein Deutscher Ingenieure; and Professor Busley, President of the Schiffbautechnische Gesellschaft. Each referred in appropriate terms to the high appreciation entertained in foreign countries of the Institution and of its work, not only in respect to the educational value of the papers contributed and the discussions which took place upon these, but also to the model constitution on which so many of the foreign institutions were founded. Like the others, Professor Busley referred to the unfailing sympathy and kindness shown to visitors at every meeting, and to the influence of personal friendships formed, which permitted a closer intimacy and more harmonious relationship, which was for the benefit of all countries. The German representatives, on behalf of their *confrères*, presented to the Institution a beautiful example of bronze statuary in the form of a craftsman.

The President, in acknowledging this magnificent mark of friendship, observed that, although he was British to the core, and proud of it, he was "made in Germany," having been born at the British Legation at Dresden, and that although he had left Germany early, he had always a warm interest in the affairs of that country. He paid a tribute to the Emperor Frederick and to the Emperor William, than whom there was no more popular monarch when he appeared in the streets of London.

The members and the guests from foreign countries partook of luncheon in the various rooms adjoining the Grand Hall, at the Connaught Rooms, and in the afternoon a visit was paid to the Exhibition at Shepherd's Bush, where the members and delegates were received by the Duke of Teck at the Garden Club. In the evening there was a reception at Lord Brassey's house at Park Lane, which has so often been the venue of such gatherings. The historic and scientific treasures of Lord Brassey's home were greatly appreciated, and, as ever, were a source of charm and interest to the large company which partook of the hospitality of Lord and Lady Brassey.

On Wednesday two sectional meetings were held between 11 and 1 o'clock, one at the Institution of Civil Engineers, and the other at the Institution of Mechanical Engineers. At the former meeting the President, the Marquis of Bristol, took the chair, and announced at the outset that the reading of Sir Andrew Noble's paper, dealing with progress in naval artillery, had been postponed until the meeting on the 7th inst.

Fifty Years' Architectural Expression of Tactical Ideas.

Admiral Sir Cyprian Bridge read the first paper, entitled "Fifty Years' Architectural Expression of Tactical Ideas." This paper is reprinted on page 37 of this issue.

The discussion was opened by Admiral of the Fleet Sir Gerard Noel, who was called upon by the President. Sir Gerard began by saying that he would have preferred that some one else than himself should speak first, as the paper appeared to be pre-eminently one on which the opinions of naval architects was desirable. He could personally vouch for the accuracy of the state of naval architecture fifty years ago, as presented in the paper, and when he looked on a famous picture representing Nelson in his cabin, he found that in almost all its details the cabin arrangement indicated might have represented those of his (the speaker's) first ship. There was undoubtedly little change in naval architecture over a long period of time, and he thought the great changes that later years had witnessed were due mainly to improvements in material, particularly in steel, which naval architects had been able to avail themselves of. Sir Cyprian Bridge had pointed out that the naval officers of early times had made their tactics to suit the vessels they had. This was very true, but it should be pointed out that officers of later days had matters much complicated for them by the fact that the material of their tactics was continually changing, and becoming obsolete. In connection with this matter it should also be pointed out that naval men were not in the habit of publishing their tactics to the world, and because an officer did not talk about his tactics, it did not follow that he had not got any. There was little doubt but that in recent years great stress had been laid on the question of the defensive features in warship construction, and he personally certainly considered the protection of the vital parts, so that ships could keep afloat, to be of the first importance.

Herr G. O. Hüllmann, Director of Naval Construction for Germany, thought that during the whole history of warship design the data on which tactics had been based were fixed by the naval architects. At the present time, however, the architects more and more wanted the assistance of naval officers. If architects were left too much to themselves now there was danger that development might tend in the wrong direction; although, similarly, if matters were left to naval officers only, they might also progress in an unsound course. It was essential that officers and architects should pull together. He had been looking yesterday at the picture of the Battle of Trafalgar in the United Service Institution, and it had reminded

him of the enormous difference in naval conditions that the advance of gun-power had made. This factor of gun-power well illustrated the necessity for officers and architects working together, as it was only by co-operation between them that a decision as to what was reasonable in that direction could be arrived at.

Rear-Admiral W. L. Capps, late Chief Constructor of the United States Navy, thought that the paper paid a profound compliment to the naval architect's profession. There was great difficulty in the naval architect getting a clear conception of what the ideals of the naval officer were. He had experienced this difficulty himself, and thought that the officer's ideals were not always crystallised. Sometimes they changed while a ship was being built. One of the greatest difficulties of the architect was in trying to carry out these ideas. Some six years ago he had prepared a memorandum for a 40,000-ton ship. From the architectural side such a development at that time would have been a straightforward matter, but many outside considerations came in, such as the questions of docks and facilities for repairs and other such matters, which had necessarily to develop *pari passu* with the size of ships. Then questions of speed, armour, and guns also came in, and the final decision as to how best to spend the money you had was in no way purely one of naval architecture. He quite agreed with Sir Cyprian Bridge that the best defence was overwhelming offence. This was the principle on which the ships of 200 years ago did themselves so much credit. They also depended much on their *personnel*, and that was very important, and introduced another condition. Ships must give reasonably sanitary conditions for their crews. Peace might last twenty years, and war only six months, and if the sanitary arrangements were not good the *personnel* would get into bad condition. The question of the lack of fixed principles among naval officers, which had been alluded to by Sir Cyprian Bridge, was one that he felt he ought not to touch. He thought he should say, however, that the question of the ultimate development of tactics was one that the future alone could decide. The results of an action between modern fleets were quite unknown, and there were, consequently, bound to be many divergent and changing views.

Rear-Admiral R. H. Bacon said that he felt considerable gratitude was owing to Sir Cyprian Bridge for his paper; indeed, even for the title of his paper, as it fixed one's ideas on the relation existing between naval architecture and tactics. He regretted, however, that the paper had not dealt with present-day ships. The sole and only object of tactics was to place your guns in the most efficient position as regards the enemy. Tactics were the handmaid of gun-fire and mobility. Up to 1850 mobility remained constant, but, with the coming in of steam, mobility continually increased up to about 1900. About that time mobility was also given to gun-fire. Guns did not change between 1600 and 1840; but even with the introduction of larger guns, the fighting efficiency was not quickly increased, because it took the *personnel* a long time to become accustomed to long-range fighting. Modern gun-fire, combined with speed, made long-range fighting possible. It was not feasible before the Dreadnought days to concentrate in one ship all the features that were necessary to take full advantage of long-range fighting, but when you had them, the combination of heavy guns with speed gave a ship which was able to comply closely with the requirements of modern tactics.

Rear-Admiral G. Dyrssen, President of the Admiralty Board of Sweden, who was the next speaker, said that he had much diffidence in speaking on the paper, as he had not read it before the meeting. He quite thought, with Rear-Admiral Capps, that the best form of defence lay in offence. He also thought the question of *personnel* of the first importance. There was a famous American admiral who said that if he got good men he would fight the enemy in paper ships. This was an exaggeration, but there was much truth in it. On the question of the various types of modern ships, he doubted if much was really settled on. Much was being done in the way of experiment, and it was doubtful if modern ships were an expression of modern tactical ideas. He thought the torpedo would exercise much influence in the future, and that those who relied on gun-power would ultimately have to modify their ideas in terms of the torpedo. In conclusion, he would repeat that the question of *personnel* was almost everything.

Professor Hovgaard said that he was a teacher at an American naval college, and that the paper would be of much value to him, as he was in the habit of giving his students lessons in naval history. He thanked the author for it. He would like to speak on the relation between tactical ideas and the cost of warships. History repeated itself, and in the 'eighties we had a somewhat similar deadlock between guns and armour to what we had to-day. There was, however, an essential difference in the two cases. In the 'eighties displacement was limited, largely by financial considerations, and naval architects could not build ships to carry the heavy armaments that are carried at the present time. The reason they did not build such ships was, however, not based on tactics. Modern developments were none the less due to tactics. If we wanted to get the full value of the heavy armaments now carried, it was necessary to introduce higher speeds and other modifications. This, of course, increased size, and he saw no reason to suppose that the limit had been reached—at least, not in the larger navies; it had in some of the smaller. In these strategic and tactical considerations determined the number of ships that were necessary, and from this, with limited resources, it was easy to see that the size of the individual ships was limited. He thought that although the large navies had not reached the limit of size, they were possibly approaching it.

Sir Cyprian Bridge, in replying, said that the subject of his paper was suggested to him by the Institution, or, rather, he should say, that he was asked for a history of tactics, but on considering the matter he found that there was not much tactics to give a history of. The history of ships, however, threw light on the history of tactics. He agreed with Rear-Admiral Capps that naval architects and naval officers did not always work together. But the important question was, what value should be given to naval officers' views. The principles of tactics did not change, and yet, as an example bearing on modern development, he would point out how frequently large modern Atlantic liners were quoted by naval officers as a proof that the limiting size of battleships had not been reached. That was all right, but it suggested that latter-day increase of size might be due to the development of naval architecture, and not to tactical needs at all. Rear-Admiral Bacon had spoken of the necessity of getting one's guns in the best position, and of mobility in fleets; but surely mobility was a relative term. Two steam fleets would be equally mobile, and he thought the whole matter ultimately came back to the *personnel*. Many years ago an Admiral had said "Give me wooden ships, and put the iron in my men." On the question of superior speed, on which Rear-Admiral Bacon made much, for instance, how were you to keep superior speed? Usually it was kept for very brief periods, and on that score, in his opinion, it could not be considered of very great importance.

The President, in closing the discussion on the paper and passing the thanks of the meeting to Sir Cyprian Bridge, said that on the question of naval officer's tactics not being fixed, he would say that from his personal knowledge this was not true of the late Admiral Tryon, who tried to copy the tactics of Nelson. None the less it was very difficult to settle tactics owing to the rapid advances which were made. The naval architects were really too good for the naval officers.

The Progress of Naval Construction in Japan.

The meeting then passed to the consideration of Rear-Admiral Motoki Kondo's paper on "The Progress of Naval Construction in Japan." In the absence of the author, this paper, which we reprint on page 15, was read by Chief Constructor Suyewo Nonaka.

The only speaker in the discussion was Professor Purvis, who said that in reference to the paragraph in the paper dealing with naval construction in private yards, he would like to point out that Japan, out of her limited programme, had recently given out two boats to be built in private yards. This policy of encouraging private building had now given Japan six yards capable of undertaking naval work.

The President, in thanking the author and the reader of the paper, referred to a paragraph in it which said that the Japanese had always been well up in all branches of handicraft. This was very true, and their wonderful success in adopting Western methods showed that if a people were well trained, they were always ready to take up any new work that came.

Experimental Tank Tests on Models of Submarines.

The third paper, "Results of Experimental Tank Tests on Models of Submarines," was then read by Mr. Mason S. Chace, its author. The paper, which we hope to reprint later, deals with experiments carried out at the United States Experimental Model Basin at the Navy Yard, Washington, and is concerned mainly with models of simple form, with bow and stern exactly alike and of canoe shape. Four models were dealt with, all derived from a parent form which was of circular cross-section. Stream-line curves and tabular data were given in the paper.

As the time available was very short, the President asked anyone who wished to speak on the paper to be very brief.

Mr. H. F. Hay said that he would just like to mention that he had been engaged on somewhat similar experiments and had dealt with both single and double models—that is, models in which the pressure hull and the external-resistance hull were both one, and models having two separate hulls—an inner circular one and an outer ship-form one. He thought the double hull not an ideal arrangement, and by modifying the simple spindle form of the pressure hull he had obtained a single hull form which appeared to have smaller resistance than any existing type of submarine. He would have pleasure in sending in further particulars of his experiments for the Transactions of the Institution.

After the thanks of the meeting had been expressed to Mr. Chace, the proceedings were adjourned.

Marine Turbines and Warship Machinery.

At the meeting held in the hall of the Institution of Mechanical Engineers, on Wednesday morning, Sir William White presided. There were four papers down for reading and discussion, three of which, being on ships' machinery, were taken together. The first was Professor A. C. E. Rateau's paper, entitled "The Rational Application of Turbines to the Propulsion of Warships." This is reprinted *in extenso* on page 31 of this issue. It was read in slightly curtailed form by the Chairman. The second paper was by the Hon. Sir C. A. Parsons, the subject being "The Marine Steam-Turbine from 1894 to 1910," while the third, by Engineer-Vice-Admiral Sir H. J. Oram, was entitled "Fifty Years' Changes in British Warship Machinery." Sir Charles A. Parsons's paper is reprinted in full on page 32, and that of Sir Henry Oram on page 18. Both papers were read by the authors, with slight omissions.

After the passing, in response to the Chairman's suggestion, of a vote of thanks to the authors, Lord Charles Beresford was invited to open the discussion. He wished, he said, to touch principally on one point, connected with the *personnel* of modern British warships. Whatever the quality of the guns or machinery provided in vessels of the Navy, there was no doubt whatever that the question of *personnel* was the most important thing of all to consider. He deplored the need for the remark in Sir Henry Oram's paper that the year 1910 marked the last "in which any engineer-officers, as they have hitherto been known, passed into H.M. Service." He wished to say that nothing could have been better than the working of the engineer's department under the old system. Was Admiral Oram satisfied with the proportion of officers to men? The figures he gave showed that the number of officers had scarcely increased, while that of the men had been greatly augmented, but the requirements of the Service had vastly grown. Japan, whose navy was maintained for peace, had a far more adequate complement than we had. The responsibility on the officers was immense. It was quite true that on an old flag-ship the engine-room complement may have consisted only of twenty men, compared with 224 of the corresponding ship of to-day; but it had to be remembered that in the old times, when it was necessary, hands were sent below from deck for trimming and other work.

Admiral H. I. Cone, of the United States Navy, said he wished to speak on Sir C. A. Parsons's remarks concerning the combination of recipro-

cating engines with turbines, or of geared turbines, or, in fact, of any device introduced with the object of improving the economy of turbines at low speeds. Were the advantages of such expedients sufficiently great to warrant the introduction of extra difficulties? Did the improved economy due to the use of reciprocating engines for low speeds compensate for the lowered efficiency of the combination at high speeds? The combination system was being tried in small high-speed vessels for the United States Navy, there being reciprocating engines for low speeds, with clutch or some connecting device whereby the engine could be thrown out at high speeds. Perhaps Sir Charles Parsons would say what disadvantages there were to this arrangement for small vessels. The combination installation on the Velox had been referred to. He would like to know why the engines were taken out of that vessel; perhaps it was because they could not get enough steam.

Mr. Borowicka, of the Austrian Navy, said he could not say the combination arrangement was making much progress with them. They did not look upon it altogether with favour, because it was complicated, and the ships of their navy did not go on long cruises or voyages, as did those of Great Britain, for instance, to the Colonies. Under these circumstances they thought that cruising turbines, combined with high-speed turbines in the same casing, best suited their requirements. Any improvement in ordinary turbine efficiency was only procurable by the introduction of special means.

Mr. Walter M. McFarland, of New York, referred briefly to the contract for the collier Neptune, which had been fitted with geared turbines, and had been given a dock trial just before he left the United States. Trouble with the air-pump had, unfortunately, delayed the complete trials, so that he had no information as to them; but he wished to say that the gear had been tested on a 40-hour continuous run at 7000 horse-power, and it was then that the figure of 98 per cent. efficiency had been obtained. He was one of the old-time officers of the United States Navy, and had been a member of the Board which sat under Mr. Roosevelt on the question of naval organisation. All their officers were now engineers. If such kindly expression had been given at that time as had been given that day by Lord Charles Beresford of the efficiency of engineers under the old *régime*, many heart-burnings would have been avoided. In response to a question, Mr. McFarland said the gearing on the Neptune was fitted with a modification of the floating cradle, embodying hydraulic cylinders.

Mr. A. E. Seaton felt that as this was not an oil-bearing country, he could not feel so keen on the oil-fuel question as some of his friends did. They had good coal, and he thought they should use that. Though the staff now provided might be ample for peace, and for cruising conditions when speeds were low and rests frequent, he was afraid it would prove insufficient for war. Admiral Oram had omitted mention of one fact connected with the introduction of the turbine—namely, the tenacity of purpose with which the campaign in its favour was prosecuted by the inventor. Had it not been for that, it might have been laughed out of use, as had been the case with other appliances. He thought in reports of trials of combined installations that care should be taken to debit each part of the system with its proper amount of steam, which should be clearly and carefully apportioned, so as to leave no vagueness as to what was and what was not included in the figures. He was in favour of the turbine because he thought it the best weapon with which to fight the internal-combustion engine.

Professor A. Rateau said he was glad of the opportunity of remarking on the development of the Parsons marine turbine, which had been extraordinary; the curve in the paper, of horse-power built, was rising at an extraordinarily rapid rate. That wonderful result was due no less to the persistency than to the inventive genius of Sir Charles Parsons. The installation on the Velox was very different from that of the French boat fitted by Messrs. Yarrow, or to that in the destroyer Chasseur, for in the former the engine was directly coupled to the turbine shaft, whereas in the latter system the engine was on a separate shaft, and worked always at its proper speed. He thought Sir Charles Parsons should have put the Rateau turbine in Class III, according to the subdivision in his paper, and not in Class IV., for his was a combination type, and had been so since the commencement of its application to marine work.

Sir C. A. Parsons said the aggregate construction had been taken as the reason for classification in the order given. In point of date M. Rateau was quite correct. The turbine would expand steam lower than the reciprocating engine, and in employing the combination principle there were any number of combinations which could be made. This system was, however, not very elastic, and was, therefore, not suitable for all warships. The reciprocating engines in the Velox would not run at a higher speed than that necessary for about 13 knots without knocking; above that they had to be disconnected. Gearing got over many difficulties, and with it it was possible to obtain economies like those procurable in land installations, with flat characteristics. Using by-passing in turbines, and running at or above the point of maximum efficiency, it was quite possible to obtain very good efficiency under all conditions. There was no more space required for geared than for ordinary turbines; sometimes even it was less, while the cost was also less. The gear design embodying three pistons under three journals was unnecessary. The floating cradle was not a good thing. All that was needed was for the pinion shaft to be allowed some end movement.

Engineer-Vice-Admiral Sir H. J. Oram was the last speaker. He said the Velox reciprocating-engines were removed because they were not powerful enough, and gave too low a speed. With regard to the Neptune he thought the number of officers and crew quite sufficient. It had to be remembered in comparing the number of officers in modern ships with the numbers in old ships that a large number of artificers were carried in the modern ship, and that they were equal in some respects to the engineering officers of the old ships.

Vibration Phenomena of Steamers.

On the termination of the discussion of the above-named papers the Chairman made a few remarks on a paper entitled "Our Present Knowledge of the Vibration Phenomena of Steamers," by Dr. O. Schlick. This paper, which was taken as read, we shall reprint in a future issue. The most interesting part, the Chairman said, of Dr. Schlick's paper was that which dealt with the vibration due to the action of the screw-propeller in water at the stern of a vessel in motion. He had been interested in that because part of the information had been secured by Dr. Schlick's help in connection with the Mauretania. There was really no vibration in the case of that ship; it was a tremor, which they wanted to get rid of. The cause of the tremor lay partly in the frictional and partly in the stream-line wake.

There was no discussion on Dr. Schlick's paper, in which the author differentiated between the vibration due to the reciprocating-engine parts and that which was purely propeller effect. The former, of course, was not present in turbine vessels, but the latter remained, and had to be dealt with in some way. The prediction that there would be no vibration in turbine vessels showed that the component influences at work were indifferently understood by persons making such statements.

Mr. A. Denny said they were making experiments on propellers. He judged from the paper that, so far, no formula of general application had been found.

The Chairman then adjourned the meeting until 11 A.M. on Thursday.

Luncheon at Lloyd's.

The Chairman and Committee of Lloyd's Register of British and Foreign Shipping entertained a large company of foreign guests and others to luncheon within their building in Fenchurch-street on Wednesday, and another company on Thursday. On the former day Mr. Thomas L. Devitt, the Chairman, presided, and, after the loyal toasts, gave "The Institution of Naval Architects," the Marquis of Bristol responding. The close association between Lloyd's and the Institution was naturally the theme of both speeches. Sir Edward Beauchamp, Bart., M.P., proposed "The Foreign Guests," and Dr. Max Predöhl, the Burgomaster of Hamburg, and Mr. A. Isakson replied. The latter, in addition to being President of the Swedish Institution of Naval Architects, is a Lloyd's surveyor.

In the afternoon there were two attractions. Many went to the Crystal Palace to the Festival of Empire and Pageant of London, being favoured by beautiful weather. A large company proceeded to the National Physical Laboratory at Bushy Park to attend the opening of the experimental tank.

The Opening of the National Experimental Tank.

The tank is practically a gift to the nation by Mr. A. F. Yarrow, who, it will be remembered, proposed, at the meeting of the Institution in Glasgow in 1901, that such a tank should be established, and a committee was then appointed to take such proceedings as were possible towards the realisation of the idea. Three years later Sir William White in a paper emphasised the value of such a tank, and suggested its location at the National Physical Laboratory, but, as with many such matters, the financial question was the principal difficulty. Mr. Yarrow, with characteristic generosity, solved the problem by offering 20,000*l.* for the construction of the tank, provided that a suitable fund could be raised for conducting the research work and for experimental investigations of a confidential character on behalf of private firms according to the accepted scale of fees. It was felt that a guarantee of 2000*l.* per annum for a period of ten years ought to be raised, and the Institution of Naval Architects succeeded in raising a fund producing 1340*l.*, the Executive Committee of the National Physical Laboratory undertaking the responsibility of finding the remaining proportion. An advisory committee, including many representatives of the Institution, was appointed, and there is special appropriateness in the completion of the scheme in the course of the interesting proceedings of this week.

The tank has already been described in ENGINEERING (see vol. xci, page 445), but it may be stated here that there are two water basins, the larger 550 ft. long by 30 ft. wide and 12 ft. 3 in. deep, and the smaller 63 ft. long, 5 ft. broad, and 3 ft. 3 in. deep. Suitable docks, of course, are arranged for storage, and for easy access to the models, which latter vary in length from 14 ft. to 20 ft. These models, which are formed by special machinery in paraffin wax, are towed along the water-way from a carriage electrically driven, which runs on rails secured on each side to the top of the tank walls. The speed of travelling can be varied from 1 ft. per second to 25 ft. per second.

At the opening ceremony, Sir Archibald Geikie, K.C.B., President of the Royal Society and Chairman of the General Board of the Laboratory, presided over a large gathering representative of every branch of scientific activity. In a brief introductory speech he referred to the importance of the occasion, the generosity of Mr. Yarrow, and offered a welcome to guests from other countries.

To Lord Rayleigh, O.M., F.R.S., as Chairman of the Executive Committee, fell the honour of declaring the tank open. In his address he passed a high encomium upon the late Dr. William Froude, for the ingenuity displayed in the application of the principles of dynamical similitude to the determination of the resistance of ship models, and in the devising of all apparatus for the purpose with a prescience of the necessities of the case which rendered any departure unnecessary, even in the light of later and extended experience. The first tank was completed in 1871 at Torquay, and there much valuable work was done up till 1879, when Mr. Froude died, since when research had been continued by his son, Mr. R. E. Froude, a Government tank being opened at Haslar in 1885. More recently similar tanks have been constructed—the first by the Dennys at Dumbarton, and others by various British firms, as well as by foreign governments and private firms. Having reviewed the history of the National Tank, and spoken of Mr. Yarrow's public-spirited munificence, Lord Rayleigh stated that it was because his friends failed to induce Mr. Yarrow to undertake the opening ceremony that the duty devolved upon him. He acknowledged, on behalf of the Executive Committee, the help given to the Committee by Mr. Froude, Dr. Glazebrook, M. Bertin, Professor Busley, Mr. Baker (the superintendent of the tank), and the engineers, Messrs. Mott and Hay. Lord Rayleigh then briefly, and with apt illustration, described the principle of dynamical similitude upon which tank experiments are based, and concluded by declaring the tank open, and expressing the hope that there would be fully realised all anticipations of a fruitful future.

Mr. Yarrow, who received a most cordial reception, next addressed the gathering. He first thanked

all who had been helpful in the realisation of the scheme, and especially Sir William White, and, proceeding, pointed to the need for a tank where shipbuilders could have tests made, if our prestige was to be maintained. He recalled the well-accepted fact of school-day experience that it was a very much easier task to get to the top of one's class than to remain there, and similarly, it must be realised that shipbuilders and engineers, if they had their country's welfare at heart, must, in addition to studying the success of their own firms, co-operate to do what was necessary for the advance of their profession, upon which the safety of our nation greatly depended. They had nothing to fear so long as the Admiralty, who had in the past led the way to progress, continued that policy, and gave encouragement to firms who had shown their keenness to initiate improvements and to lead rather than to follow. It was good to see firms keenly competing in the work of invention and improvement, but if those firms had to give up this policy and were forced to turn their attention solely to the reduction of cost, our prestige as a nation taking the lead in naval advance, would most certainly fall into other hands. There appeared a tendency to discourage special originative work, which was the secret of success, and to devote more attention to meet the immediate demands of greater competition, and to securing reduction in price. If this policy were carried too far, it would be fatal to future progress. This striving after cheapness would lead to the inevitable result of securing present gain at the sacrifice of future progress; for it must be borne in mind that if contractors were deprived of the margin of profit which enabled them to make investigations, it would put a stop to their enthusiasm in scientific advance. In conclusion, he said that he felt it a great privilege to have been the means of assisting to found the National Experimental Tank, which he hoped and trusted might not only be an advantage to the profession which was so dear to his hearers, but also to the country to which they were all so proud to belong.

The Marchioness of Bristol then set in motion the carriage towing a model in the tank, and it traversed the full length of the basin. On its return, the Marquis acknowledged the honour conferred upon his wife, and spoke of the practical utility of the research work to be undertaken in the tank.

Sir William White expressed the hope, on behalf of the Institution and of Mr. Yarrow, that the tank might be known as the "Froude tank," and the suggestion was approved by applause.

The guests afterwards visited other departments of the Laboratory, and took tea, which was served in the grounds, returning to town by special train. In the evening a festival concert in the Queen's Hall was largely attended, the Leeds Festival Choir, under the conductorship of Sir Charles Villiers Stanford, D.C.L., being the principal attraction. Supper was served later at the Queen's Hall, and Sir William White, in the course of the proceedings, proposed the health of Sir Charles Stanford, and Mr. Dana, the secretary of the Institution.

With the proceedings of yesterday, to-day, and to-morrow we shall deal in our next issue.

(*To be continued.*)

INDUSTRIAL NOTES.

AT the end of last week the gravity of the situation created by the seamen's strike had in no wise decreased, for although the seamen and firemen themselves appear to have been willing to accept terms, they would not do so on account of their being in sympathy with the dock labourers who were also on strike. In Hull, where the greatest trouble had been experienced, and where serious rioting had taken place, things were quiet at the end of the week, probably due to the importation into the town of 500 men of the London police. Put briefly, the situation at the end of last week was that the negotiations for a settlement had been broken off at Hull and things wore a threatening aspect, the men being held in check by the strong show of force in the town. In London, where the effects of the strike had not been much felt, a great dock strike was threatened, the men having put forward demands for an increase of (on the minimum wage) from 6d. an hour to 8d. with 1s. an hour for overtime. The terms agreed to by the men's officials in Liverpool were not accepted by 2000 of the men. Altogether, at the end of the week the outlook was gloomy.

It was known on Saturday that about half the shipowners in the country had formulated their scale of wages in accordance with the resolution arrived at during the conference held in London on Wednesday. These, speaking generally, represent an increase of about 10s. per month to the seamen. The rates agreed upon for crews signing on at Manchester were fixed on Friday as follow:—(1) General coasting trades, 29s. and the usual extras weekly. (2) Regular coasting and Continental liners, 32s. 6d. weekly. (3) Baltic, Eastern, Mediterranean, and South Atlantic: Seamen, 4*l.* 10s. monthly; firemen, 4*l.* 15s. monthly. (4) North Atlantic and St. Lawrence: Seamen, 4*l.* 10s. monthly; firemen, 5*l.* monthly. In Nos. 3 and 4, provisions to be found by the owners; No. 1, to remain as before. No. 2 represents an increase of 2s. 6d. per week for both seamen and firemen, while Nos. 3 and 4 represent an increase of 10s. monthly for both seamen and firemen. This scale was, however, refused by the men's leaders, who said they would not be satisfied with less than an advance of 5s. for weekly boats and an average up to 5*l.* 10s. for monthly boats.

The beginning of this week brought hope that matters would soon be settled satisfactorily and peace restored, for on Monday the outstanding differences between the shipowners and the men on strike in Liverpool and Hull were to a large extent settled. At other ports also, where the unsettlement had been less acute, this was also the case. At Hull, at the conference between the representatives of the employers and employed, under the presidency of Mr. Askwith of the Board of Trade, terms were arranged according to which the men agreed at once to return to work, having received considerable concessions. This, however, does not include 900 flour-millers, who are not yet satisfied with the offer made them. In Liverpool the outlook improved, but in Manchester things were less favourable, for there 4000 carters and several hundred railway employees came out on strike. At Bristol and Newcastle also the quay labourers refused to work incoming boats that had been diverted from other ports. In Hull the strikers who returned to work on Tuesday morning numbered about 20,000. They have not obtained all they asked for, but the wages of each class are increased, and the conditions of work are improved, and the men appear quite satisfied. The weekly wages of seamen at Hull and Goole will be 32s. 6d., and the monthly rates for firemen will be 4*l.* 15s. Questions relating to the Federation ticket, doctors' examination, and a weekly half-holiday, have also been settled. The case of dockers, and other shore workers was also settled, the men obtaining an additional ½d. per hour. In addition, the employers agree to meet the representatives of sections of workpeople as well as the chief classes concerned in the strike in order to discuss claims, a reasonable notice being given. The final clause of the agreement is, perhaps, the most important, as it relates to the interests of the community as a whole. It runs: "In the event of any question arising as to the interpretation of any clauses of this agreement, which cannot be settled by the parties concerned, no stoppage of work shall take place, but the matter shall be referred to the Board of Trade." Although the famine prices charged for flour in Hull on Saturday no longer hold, the price of flour is still high. This high price has, however, been largely due to the sectional strike of 900 millers.

In Liverpool practically the only men now out are a few scalers, who are mostly young fellows demanding increased pay, and some two or three hundred mates, second engineers, and seamen employed by the Alexandria and Cock Towing Companies. It is stated that, as a result of the strike, some 8000 men have joined the Dockers' Union, and there have been large additions to the Seamen's and Stewards' Unions. At the time of going to press Manchester was in a state of turmoil, the strike having resulted in rioting and bloodshed, and the strike in Glasgow had been renewed when the dockers, firemen, stewards, and cooks of the Allan and Anchor Lines came out. They refuse to go back till the quay labourers' terms have been met.

The twelfth annual report of the General Federation of Trade Unions has recently appeared, and shows a record of a very trying period in the history of the Federation; in fact, the financial reserve was less than at any time since 1902. The boilermakers' dispute alone cost the Federation over 53,000*l.* On March 31, last year, there were 135 societies on the books of the Federation, but during the year five societies left, the total membership at the end of the year being 697,391. During the year ending March 31, 1911, there were additions to the Federation which brought the membership up to 710,994. The report shows that the income, both from contributions and from interest, is lower by 1650*l.* 4s. 9d. than last year, the decrease being accounted for by the fact that in 1909-10 the boilermakers paid five quarters while in 1910-11 they only paid three, and the loss of income on investments is due to the withdrawals on account of Federation benefit. The total expenditure for the year was 74,952*l.* 17s. 11d., or an excess of expenditure over income of 39,648*l.* 14s. 2d., which excess was due to the claims made for benefit, for although the actual disputes were fewer than in 1909-10 the number of workers involved rose from 6418 to 23,635, and the cost of disputes rose from 8767*l.* 18s. 1d. to 72,321*l.* 19s. 10d. Disputes during the year affected 3.32 per cent. of the total membership of the Federation, and the average payments per head of those involved have exceeded 3*l.* 1s. 2d. All other expenditure shows a decrease of 17½ per cent. A comparison of income and expenditure covering the whole of the Federation's existence shows that the amount actually returned to the members in Federation benefit, 288,576*l.*, plus the balance of 61,235*l.*, exceeds the amount actually received in contributions and entrance fees (335,816*l.*) by 13,995*l.* The total reserve fund now stands at 61,235*l.* 7s. 7d., part of which, amounting to 10,486*l.* 15s. 1d., is practically at call, while the balance can be realised on six months' notice.

The South Wales Miners' Federation held a general conference of lodge delegates at Cardiff on Saturday last, when the general feeling of the delegates appears to have been that pressure should not be put on the Cambrian men to return to work, but that earnest efforts should be made to support them by levies, at least until after the National Conference to be held in London on July 28. The weekly grant ceased on Saturday last, but there are hopes among the men that it will be restarted. The question of a general Welsh strike was discussed, but no actual resolution was put to the meeting. It was, however, agreed to issue a manifesto to the English and Scottish miners explaining the position in South Wales, and also to send men to place the facts before the workmen. It was the feeling of the meeting that sectional fighting was no use, and that a national strike was the only way to secure a redress of grievances.

The conciliation board of the Northumberland coal trade met at Newcastle on Saturday last, and decided that with pays beginning on the following Monday and on July 10 the wages of underground workmen and "banksmen" be advanced by 1¼ per cent., making them 27½ per cent. above the basis of 1879. The wages of other classes of labour advanced in the usual proportion will be 22 per cent. above the standard. It is stated that, unless some agreement be arrived at within the next three months, there will be no further meeting of the board, as the miners have given notice to secure a minimum wage of 30 per cent. above the standard of 1879.

The labour conflicts, both in Sweden and Norway, are assuming a more serious form. In the first-named country the negotiations within the building trades have led to no results, and as the current strikes have not been terminated the Central Union of Swedish Employers has given notice that the Union, in order to defend its members, whose men have gone out on strike, has found it necessary to declare a lock-out, as far as all the members of the Union are concerned, from Monday, July 10. Further mediation, however, is likely to be attempted. Should it not succeed, some 40,000 men will be locked out. In Norway, mediation has been resorted to in vain, and no agreement having been arrived at by July 1, the Union of Norwegian Employers on that extended the notice of lock-out, so as to comprise some additional 16,000 hands. This second lock-out refers to 139 industries, viz., the iron industry as a body, and the following in the paper-making industry:—the Union Company, Skien; the Klosterfossen Company, Skien; the Embretsfos Company, Modum; the Hlunsfos factories, Christianssand.

THE JUNIOR INSTITUTION OF ENGINEERS.—The summer meeting of this Institution will take place at Felixstowe, Ipswich, Norwich, and Cambridge, from July 29 to August 5. Visits to various works are being arranged, also to the engineering laboratories, workshops, and colleges at Cambridge. In the evening of Friday, August 4, the Institution's summer dinner will be held at the University Arms Hotel, the President, Sir J. J. Thomson, F.R.S., being in the chair. The necessary arrangements are being carried out by the Secretary, Mr. Walter T. Dunn, 39, Victoria-street, Westminster.

THE LATE DR. G. J. STONEY.—We regret to announce the death of Dr. George Johnstone Stoney, F.R.S., which occurred on Wednesday, at his residence in London, in the eighty-sixth year of his age. The deceased gentleman made many valuable contributions to physics, and to him indeed is due the introduction of the term "electron" for the unit disembodied charge of electricity. At an earlier date in his career he served on the British Association Committee which introduced the now recognised system of electrical and magnetic units. He was elected a member of the Royal Society in 1861, and served long as a member of the Council, of which he was afterwards appointed one of the vice-presidents. His brother, Bindon Blood Stoney, was well known as engineer to the Dublin Port and Harbour Board. Mr. Gerald Stoney, F.R.S., who has been so closely associated with he development of the Parsons steam-turbine, is his son.

NOTES FROM THE NORTH.

GLASGOW, Wednesday.

Glasgow Pig-Iron Market.—Last Thursday morning the pig-iron market opened with a firm tone, and 5500 tons of Cleveland warrants were done at 46s. 3½d. cash and 46s. 6d. one month. Closing sellers quoted 46s. 4d. cash, 46s. 7d. one month, and 47s. 0½d. three months. In the afternoon the market was steady, but no dealings were recorded. At the close of the day there were sellers at 46s. 4d. cash, 46s. 7d. one month, and 47s. three months. On Friday morning a stronger tone prevailed, and although the business was limited to two lots of Cleveland warrants, they were done at 46s. 5d. cash, and 47s. 1½d. three months. Sellers' closing prices were 46s. 5½d. cash, 46s. 8d. one month, and 47s. 1½d. three months. The afternoon session was easier in tone, and a small business of 1500 tons of Cleveland warrants changed hands at 46s. 4½d. cash, with sellers over at that figure, and at 46s. 7½d. one month, and 47s. 1d. three months. On Monday morning there was little life in the market, and the dealings consisted of only two lots of Cleveland warrants at 46s. 7d. one month, and at the close sellers quoted 46s. 4d. cash, 46s. 7d. one month, and 47s. 0½d. three months. In the afternoon quietness was again the ruling feature, and the turnover consisted of 1500 tons of Cleveland warrants at 46s. 6½d. one month, and closing quotations were 46s. 4d. cash, 46s. 7d. one month, and 47s. 0½d. three months sellers. On Tuesday morning there was no change in the tone of the market, and only one Cleveland warrant changed hands at 46s. 6d. one month. Closing prices were easier, at 46s. 3½d. cash, 46s. 6½d. one month, and 47s. three months sellers. Cash sellers of hematite quoted 61s., but there were no buyers. The afternoon session was dead idle, but sellers of Cleveland warrants quoted nominally ½d. up, at 46s. 4d. cash, 46s. 7d. one month, and 47s. 0½d. three months. When the market opened to-day (Wednesday) the tone was the turn stronger, and some 3500 tons of Cleveland warrants were done at 46s. 6½d. and 46s. 7d. one month. Closing sellers quoted 46s. 4½d. cash, 46s. 7½d. one month, and 47s. 1½d. three months. Hematite was quoted at 60s. cash buyers and 60s. 10½d. cash sellers. In the afternoon business was quite at a standstill, but quotations for Cleveland warrants were nominally steady, with sellers at 46s. 4½d. cash, 46s. 7½d. one month, and 47s. 1½d. three months. The following are the market quotations for makers' (No. 1) iron:—Clyde, 60s. 6d.; Calder and Gartsherrie, 61s.; Summerlee, 63s.; Langloan, 64s.; and Coltness, 82s. 6d. (all shipped at Glasgow); Glengarnock (at Ardrossan), 64s.; Shotts (at Leith), 62s.; and Carron (at Grangemouth), 63s.

Sulphate of Ammonia.—A better inquiry exists for sulphate of ammonia this week, and the price is firmer. The current quotation for prompt lots is now 13*l.* 7s. 6d. per ton, Glasgow or Leith.

Scotch Steel Trade.—No change falls to be reported in connection with the state of the Scotch steel trade, with the exception that a little activity is noticeable in the clearing off of orders before closing down for the holidays, and there is a consequent increase in specifications. The shipbuilding yards in the lower reaches of the Clyde knock-off for holidays at the end of this week, and will have resumed work before the steel trade, so that specifications from that source for plates, angles, &c., are also rather better at the moment. On the other hand, no increase in new business has taken place, and buyers continue to pursue the policy of waiting for a fall in prices, which, however, has shown no signs of coming. Light steel material of all kinds and structural sections are in good demand, especially the former.

Malleable-Iron Trade.—The malleable-iron trade of the West of Scotland is practically without change, and the basis price for Crown bars is still 6*l.* per ton, less 5 per cent. for prompt delivery.

Scotch Pig-Iron Trade.—A fairly good business has lately been done in the ordinary qualities of Scotch pig-iron, principally with buyers in the South, but local consumers continue to purchase sparingly. The export demand is satisfactory, but owing to the trouble with the seamen and quay labourers, deliveries are being somewhat delayed. Hematite is still inactive, and no change has taken place in prices.

Shipbuilding.—The shipbuilding returns for the past month are very satisfactory, and bring up the output of the year to date to quite a respectable tonnage. The following are the figures for the different Scotch districts:—

	June, 1911.		Six Months, 1911.	
	Vessels.	Tons.	Vessels.	Tons.
The Clyde	23	52,474	135	309,860
The Forth	3	1,345	13	6,756
The Tay	..	..	9	8,807
The Dee	5	598	39	5,862
Total output ..	31	54,417	196	331,285

It is interesting to note that the June output for the Clyde yards is over the average for the six months just closed, and also that it brings the total for the year to date up to 309,860 tons. Only on one occasion has the output for the same period been greater, and that was in 1906—the year of the "Lusitania"—when the total figures amounted to 336,258 tons. A record may not be created this year, but if labour troubles are only overcome, there is likely to be quite a large output marked up against the year 1911. New orders are scarce at present, but contracts on hand ensure steady employment for some months ahead. It is just reported that the contract for the two new Empress steamers for the Atlantic service of the Canadian Pacific Railway Company has been secured by the Fairfield Shipbuilding and Engineering Company, Limited, Govan.

NOTES FROM SOUTH YORKSHIRE.

SHEFFIELD, Wednesday.

National Insurance and Industry.—At the annual meeting of shareholders of Messrs. John Brown and Co., Limited, held in Sheffield, the chairman pointed out that, with their subsidiary concerns, the company employed between 40,000 and 50,000 men—wage-earners; and when they came to reckon up what the National Insurance charge would involve, it meant that something like 25,000*l.* a year would have to be found by the company. This amounted to about 1½ per cent. of their capital, or, to put it in another way, they would see 1½ per cent. taken from their dividends. Of course, that was perhaps, taking the worst view of the situation, but it was only right that shareholders should understand what these latest legislative projects really meant. In a short time they might be able to throw that charge on the cost of production, as in the case of the Compensation Act, but they must not be surprised if, during the first twelve months, it had a very serious effect upon their revenue.

Iron and Steel.—Half-yearly stocktaking has been responsible for an almost total suspension of buying during the past week, and the raw material market has been exceptionally quiet. Prices have remained at a dead level for some weeks past, and there is little prospect of any immediate alteration. The general tone of the market, however, is hopeful. Contracts are running out, and with stocks very low, manufacturers will shortly be compelled to replenish. The heavy output of manufactured iron and steel indicates a strong revival when consumers do come on the market. Lincolnshire irons, with little doing, show no change. Derbyshire makers, owing to the lower prices, are more favourably situated. Foundry sorts are making 50s. to 51s. The engineering houses are well supplied with orders, in many cases working overtime, but complaints are still rife of the unremunerative character of much of the work. Keen competition from abroad, and cutting at home, leave but little margin for profit, and with wages showing an all-round increase, the earnings of even those houses having important specialities are comparatively small for a time of such activity.

South Yorkshire Coal Trade.—Latest quotations are as follows:—Best branch hand-picked, 13s. to 14s.; Barnsley best silkstone, 11s. to 12s.; silkstone, 9s. to 10s.; Derbyshire house, 8s. to 9s.; large nuts, 7s. 3d. to 9s.; small nuts, 5s. 6d. to 6s. 6d.; Derbyshire brights, 10s. 3d. to 11s.; Yorkshire hards, 8s. 3d. to 9s. 6d.; Derbyshire, 8s. to 9s.; washed nuts, 7s. 9d. to 8s. 9d.; rough slacks, 5s. 3d. to 7s.; seconds, 4s. to 5s.; smalls, 1s. 6d. to 2s. 6d.

THE KAISER WILHELM CANAL.—The traffic through the Kaiser Wilhelm Canal, which dropped off in 1908, but recovered in 1909, continued to increase during 1910. Altogether 75,569 vessels, aggregating 7,579,339 registered tons, passed through the Holstein Canal, against 36,547 vessels, of 6,527,698 tons, in 1909. The number of steamships shows a very considerable increase, from 16,821 in 1909 to 21,033 in 1910, while the number of sailing vessels has actually decreased, from 18,334 in 1909 to 17,450 in 1910. Lighters, &c., have also increased, both in number (7086 against 3391) and in capacity (1,148,690 against 723,557 registered tons). The ships of the German Navy are not comprised in these statistics.

THE IRON AND STEEL INSTITUTE MEETING: THE TURIN MEETING.—Arrangements have been made to hold the Autumn Meeting of the above Institute at Turin on Monday and Tuesday, October 2 and 3, this year, when the following papers will, it is expected, be read:—(1) "Report on the Mineral Resources of Italy," by various authors; (2) "On the Autogenous Welding of Metals," by Dr. Francesco Carnevali (Turin); (3) "On the Application of Electrical Energy to the Manufacture of Iron and Steel in Italy," by Cav.-Ing. Remo Catani; (4) "On the Present State of the Iron and Steel Industries of Italy," by Signor Comm. Luigi Dompé and Cav. Francesco Sayerio Pucci; (5) "On New Industrial Processes for the Cementation of Steel," by Cav. Prof. Dr. Federico Giolitti; (6) "On Cementation with Gas Under Pressure," by Prof. Dr. F. Giolitti and Dr. Francesco Carnevali; (7) "On the Transformation of Steel Within the Limits of Temperature Employed for Heat Treatment," by Louis Grenet (Argenteuil, France); (8) "On Basic Slag," by V. Adolphe Kroll, Junr. (Frankfort-on-Main); (9) "On the Use of Titanium in Iron and Steel," by C. V. Slocum (Pittsburg); and (10) "On the Physico-Chemical Properties of Slag," by Prof. J. H. L. Vogt (Christiania). Members will, however, receive a final list of papers later. The following is a brief programme of the arrangements for travelling, &c.:—Members resident in Great Britain can travel together, and in order to avoid night travelling on the outward journey the party will stay one night in Paris and one night at Aix-les-Bains. Special reduced fares have been fixed in connection with these arrangements. The train will start from Holborn Viaduct (South-Eastern and Chatham Railway) at 9.30 a.m., on September 29, and passengers are expected to arrive at Turin on October 1, at 6.10 p.m. On October 1 and the two succeeding days badges and programmes will be distributed and members will be welcomed by the civic authorities; papers will be read and discussed, and places of interest visited on October 4 and 5. There will be excursions to Savona and Genoa, and from then to October 17 there will be visits to Rome, Naples, Terni, Florence, and Milan. There will also be a special excursion to the Island of Elba and to Piombino, on Friday and Saturday, October 6 and 7. Further particulars may be obtained from the secretary, Mr. G. C. Lloyd, 28, Victoria-street, Westminster, S.W.

NOTES FROM CLEVELAND AND THE NORTHERN COUNTIES.

MIDDLESBROUGH, Wednesday.

The Cleveland Iron Trade.—The pig-iron market is still dull, but values of Cleveland kinds are rather stronger. Makers are not very keen sellers, as they anticipate improvement in values in the near future. Transactions are consequently confined to sales for early delivery, and it is significant that sellers will not quote forward except at higher rates than rule for early business. Production is now fairly well taken up, and as the autumn approaches the make should be more than fully absorbed, and stocks consequently reduced; but it must be borne in mind that we are still passing through what is usually a quiet period of the year. The better reports from the United States should assist to strengthen this market. No. 3 g.m.b. Cleveland pig is 46s. 7½d. f.o.b.; whilst No. 1 is 50s. 1½d.; No. 4 foundry, 46s. 1½d.; No. 4 forge, 46s.; mottled and white each 45s. 9d.; and Nos. 1, 2, and 3 East Coast hematite pig 61s. 6d.—all for early delivery. Business in foreign ore is still at a standstill. Prices show a rather downward tendency, but consumers declare that very substantial reductions will yet have to be made before a renewal of buying is at all likely. Rubio, of 50 per cent. quality, is quoted 19s. to 20s. ex-ship Tees. Coke is in fairly good request, the local consumption being heavy, and demand for shipment is fairly good, but the supply is ample. Average blast-furnace kinds are not more than 14s. 6d. delivered here, and foundry coke ranges from 16s. to 17s. f.o.b.

Manufactured Iron and Steel.—Though new orders are by no means plentiful, producers of nearly all descriptions of manufactured iron and steel are pretty well placed, several firms having made contracts which will keep them employed for some months. Manufacturers, under these conditions, are not pressing sales particularly, as they hope for improvement in values. Principal market quotations stand:—Common iron bars, 7*l.*; best bars, 7*l.* 7s. 6d.; best best bars, 7*l.* 15s.; packing-iron, 5*l.* 15s.; iron ship-plates, 6*l.* 12s. 6d.; iron ship-angles, 7*l.*; iron ship-rivets, 7*l.* 5s.; iron boiler-plates, 7*l.* 7s. 6d.; steel bars, 6*l.* 5s.; steel ship-plates, 6*l.* 15s.; steel ship-angles, 6*l.* 7s. 6d.; steel boiler-plates, 7*l.* 10s.; steel strip, 6*l.* 10s.; steel hoops, 6*l.* 12s. 6d.; steel joists, 6*l.* 7s. 6d.; cast-iron railway-chairs, 3*l.* 12s. 6d.; light iron rails, 6*l.* 10s.; heavy steel rails, 5*l.* 12s. 6d.; steel railway sleepers, 6*l.* 10s.; and iron and steel galvanised corrugated sheets, 10*l.* 15s.—sheets less 4 per cent., railway material net, and all other descriptions less 2½ per cent. discount.

Shipments of Iron and Steel.—June shipments were but small. This was what was anticipated, for June is usually a quiet shipping month, and this year loadings were checked by the Coronation holidays, and by the unfortunate seamen's strike. Pig iron cleared during last month averaged 4509 tons per working day, the total despatches being returned at 108,219 tons, 95,713 tons of which went from Middlesbrough and 13,506 tons from Skinningrove. For the previous month the total clearances of pig reached 142,559 tons, or a daily average of 5317 tons, and during June, last year, the despatches amounted to 117,957 tons, or an average of 4537 tons per working day. Of the pig iron sent from Skinningrove last month 12,430 tons went to Scotland, and 1076 tons to the Continent. Of the pig iron sent from Middlesbrough last month 75,523 tons went abroad, and 20,190 tons to coastwise customers. Japan was the largest receiver, taking 13,801 tons; whilst Italy took 12,293 tons; Germany, 11,638 tons; Scotland, 10,814 tons; and Canada, 7265 tons. Shipments of manufactured iron for June were given at 12,013 tons, 6071 tons going foreign, and 5942 tons coastwise, India once more being the largest customer with an import of 4035 tons. The steel cleared last month amounted to 28,354 tons, 23,216 tons of which went abroad and 5038 tons coastwise. The best customers were Canada, 4459 tons; India, 4449 tons; Japan, 3969 tons; and Victoria, 2203 tons.

THE MIDLAND INSTITUTE OF MINING, CIVIL, AND MECHANICAL ENGINEERS.—The annual general meeting of the members of the above Institute will be held at the Philosophical Hall, Leeds, on Tuesday, July 18, at 3.30 p.m. The paper to be read and discussed at the meeting is on "Coal-Dust Experiments," by Mr. W. E. Garforth.

"ALL ABOUT PATENTS."—This is the title of a practical guide, in pamphlet form, for inventors, patentees, investors and manufacturers, by Mr. Clarence W. Crossley, issued at the price of 9d. net. It deals with a number of points of interest to the classes addressed, concerning inventions, patents covering same, and the working and sale of the latter.

CONTRACTS.—We are informed by the British Westinghouse Electrical and Manufacturing Company, Limited, that they have recently received a number of important orders, among which are:—Three 400-kw. rotary converter sets for the Tyneside Electric Development Company, Horden and Shotton Colliery; three 450-kw. rotary converter sets direct-current switch gear, &c., for the Greenock Corporation; one 500-kw. rotary converter and switch-gear for John Summers and Co., Limited; fifty magnetic brakes for the Manchester Corporation; one 2000-kw. 3000-revolutions per minute alternating-current turbo-generator set, with surface-condensing plant, &c., for the Blackburn Corporation; and one 1500-kw. high-pressure turbine (Impulse type) coupled to one 1600-kw. direct-current generator, and one 1100 alternating-current generator in tandem, with surface-condensing plant, Lea recorder, and Brown-Boveri regulator,

LARGE CRANES.

TO THE EDITOR OF ENGINEERING.

SIR,—With reference to the description of the 200-ton electric Titan crane at the Fairfield Works, given in last week's ENGINEERING, we observe it is there stated that "No larger crane has, so far, been constructed." We would, however, point out that this is not the case, as there are already two larger cranes in operation, one of these being at His Majesty's dockyard, Devonport, and the other at the Imperial Japanese Navy dockyard, Yokosuka, both of which were designed and manufactured by us.

The following table will show the respective powers of these cranes in foot-tons :—

	Tons.	Radius, Feet.	Foot-Tons.
Fairfield Crane.			
Working load ...	200	75	15,000
Test load ...	250	75	18,750
Devonport Crane.			
Working load ...	160	95	15,200
Test load ...	240	95	22,800
Yokosuka Crane.			
Working load ...	200	95	19,000
Test load ...	250	95	23,750

Yours faithfully,
For COWANS, SHELDON, AND CO., Limited,
J. W. BROWN, Secretary.

Carlisle, July 3, 1911.

ST. PAUL'S BRIDGE.

TO THE EDITOR OF ENGINEERING.

SIR,—It appears the City is appointing three architects in reference to the above as a committee. But why not a composite one, with representatives of engineering and surveying as well? The addition of a well-known business man also would be an acquisition, together with someone who has shown special acquaintance with the whole aspect of the question. It is not merely to the "make-up" of the committee that objection can be taken, but to the matter of its origin. True, the City is generously offering to build a bridge, and naturally has undertaken the ordering of it, on what it believes to be the best lines. In doing so it is feared the matter is being considered as merely local, whereas it is at least metropolitan, if not national or imperial. It appears to be viewed also in its most limited aspect, as simply the matter of a bridge and its connections, whereas in the ultimate it is the question of at least a new main thoroughfare from the "Angel" to the "Elephant"—alternative, perhaps, to the proposal of the Royal Commission on London Traffic for a new north to south main avenue.

It seems to be forgotten, in fact, that we are in the midst of designing a new Metropolis, and must say good-bye to the practices of the past, in which one piece after another has been added without even general reference to the whole and to what may be expected to come after. Begun by the above Royal Commission, continued in a branch of the Board of Trade (perhaps also in some measure in the Roads Development Commission), the new draft plan may be said to be well on the way. But we still await the appointment of the body destined to formulate definitely the working plan for the reconstruction of the Metropolis in fulfilment of the recommendation of the Royal Commission.

Listening to the debate on the New Bridge Bill in Parliament, it was noticed as strange that the above matter was not once referred to; and, marvel, no Government oracle ventured a syllable on either question, surpassingly important as both are in relation to the Metropolis of the future.

Any reference, it is considered, which the City can impose on such a committee of its appointment must necessarily be very limited, even if it goes beyond the locale of the proposed bridge in the City. Whereas, it has been shown that the general question at issue stretches far beyond the City's nominal interest and jurisdiction. In view of that, therefore, any findings of such a committee must be considered unsatisfactory.

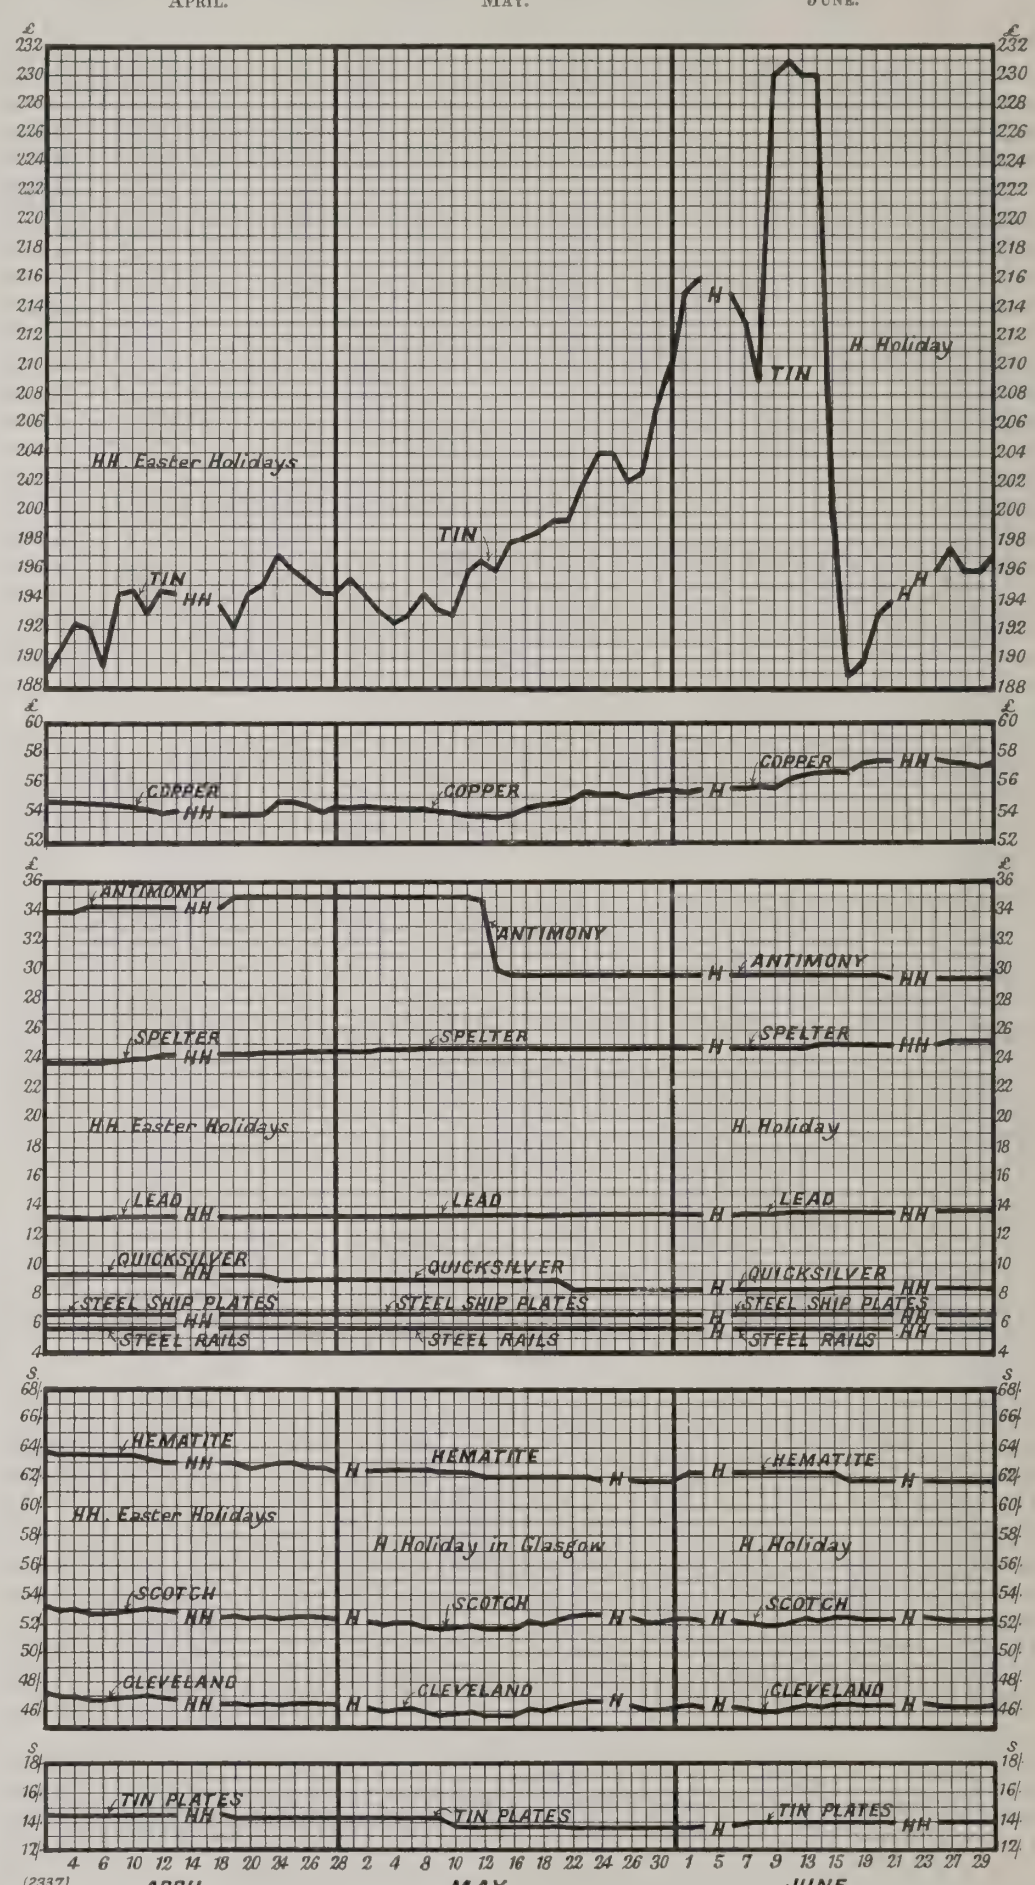
As a solution of the matter it is reckoned that the City, having acted so nobly, would, under the circumstances, be well advised to as gracefully withdraw from further contention. The onus of carrying the matter through as a whole would thus be left to Government and the prospective new body which could consider the project in its widest aspect, and carry it out as part of a well-devised general plan of the new Metropolis.

Yours truly,
London, July 3, 1911. O.B.I.T.

LONDON, TILBURY, AND SOUTHEND RAILWAY.—The proposed transfer of the London, Tilbury, and Southend Railway to the Midland Railway Company has been almost unanimously approved at a meeting of the present proprietors; and, subject to the approval of Parliament, the amalgamation may almost be regarded as a *fait accompli*. The Tilbury line was originally leased to Messrs. Peto, Brassey, and Betts, the contractors who built it, and who guaranteed an interest of 6 per cent. per annum upon the share capital for a term of fourteen years. In 1876 the guarantee expired, and the London, Tilbury, and Southend Railway Company, which had been incorporated in 1862, had to make the best of the property. The growth of Southend during the last thirty-five years has been very great, and the Tilbury system has, accordingly, become a solid and successful undertaking. The Tottenham and Forest Gate Railway, which connects the system with the Midland Railway, has been in operation since 1894. The object of the Midland Company in acquiring the London, Tilbury, and Southend lines is to obtain further access to the coast, so as to develop more watering place traffic. The original Midland undertaking was quite land-locked, but the Midland company has been gradually pushing to the coast; and it will now, no doubt, make great efforts to render Southend an even more attractive watering place than it is at present.

DIAGRAMS OF THREE MONTHS' FLUCTUATIONS IN PRICES OF METALS.

(Specially compiled from Official Reports of London Metal and Scotch Pig-Iron Warrant Markets.)



(2337)

IN the accompanying diagrams each vertical line represents a market day, and each horizontal line represents 1s. in the case of tin-plates, hematite, Scotch and Cleveland iron, and 1*l.* in all other cases. The price of quicksilver is per bottle, the contents of which vary in weight from 70 lb. to 80 lb. The metal prices are per ton. Heavy steel rails are to Middlesbrough quotations. Tin-plates are per box of I.C. cokes.

TURBINES IN WARSHIPS.

*The Rational Application of Turbines to the Propulsion of Warships.**

By A. C. E. RATEAU, Member.

DURING the last ten years we have assisted at a considerable development of turbine engines in all navies. The success of these engines has been assured, because they are the only ones which enable us to solve the problem of speed, since the demand for high speed in every class of vessel increases daily. They have, however, other qualities which add considerably to the value of ships fitted with these engines. These qualities are principally endurance, the elimination of hull vibrations, economy of fuel at high speeds, and the fact that the engines are always ready and require no overhauling. Great importance must have been attached to these qualities to justify the adoption of these engines, as they have the grave fault of showing a low efficiency at ordinary speeds, which reduces by one-half one of the principal factors of the naval value of ships—viz., the radius of action

This reduction in radius of action does not have the same importance for all naval Powers. To Great Britain, whose wise policy has given her in all the seas of the world bases of supply not far distant from one another, endurance and constant readiness for action are qualities undoubtedly preferable to all others; consequently, the British Admiralty adopted turbines as soon as they were available, and they can, even now, continue to use them without other inconvenience than the extension of the fuel supply and the improvement of the means of utilising the same.

Other nations are not in the same position as regards turbines. They would have to provide in times of war the important convoys of supply, which, however well organised they may be, would form but an uncertain means of assistance, and would reduce the offensive naval war strength of the fleet by the number of the fighting units necessary for their protection. For these nations, therefore, the adoption of turbines has, far more than for Great Britain, meant increased expenditure, and they also have to suffer inconveniences of a strategical nature, which the greatest financial sacrifices can only reduce.

It is not surprising to find that some countries openly regret having followed the example of Great Britain, and that one of the most powerful of these is about to replace turbines by reciprocating engines for her new battleships. One may well hesitate to adopt such a radical course as to forego the advantages of turbines. Makers of turbines are, therefore, endeavouring to make these engines more economical at low speeds. The solution of the problem has been sought by making the propeller shafts revolve independently, so as to keep the turbines at a constant speed of rotation, thus securing a good efficiency; the transmitting gears are in such cases designed with toothed wheels or electric motors. Even admitting that by the introduction of these means of transmission there will not be a considerable loss of efficiency, their employment will always entail a certain complication and weakness, and the machinery so designed will lose two qualities that are most highly appreciated—viz., strength and simplicity.

In the present paper it is proposed to leave out of consideration these methods of transmission, and to keep to the study of what may be done with steam-engines only, turbines, and piston engines. By suitably combining them, it appears possible to improve greatly upon the actual consumption of steam, especially at reduced speeds. Turbines are now as well understood as reciprocating engines. We know that from the point of view of efficiency their advantages are limited by certain conditions. The piston engine has, in fact, an excellent efficiency when the steam has a mean pressure of 15 lb. to 30 lb. per square inch, but it becomes bad if the expansion is carried too far.

To utilise the expansion up to pressures approaching those obtained in the condensers, we must have cylinders of large dimensions, the attainment of which is impossible, and in which, moreover, friction losses and condensation would absorb the theoretical gain obtained by the increase of expansion. Turbines, on the contrary, have their best efficiency at low pressures, and are able to utilise the expansion beyond the condenser pressures; while they give rise to great losses at high pressures, due to the friction of the revolving parts in the steam space, also to leakages through the clearances between the moving and stationary parts. Marine turbines are further restricted to low velocities, instead of being able to utilise those which are best for a good efficiency. It is obvious, therefore, that, if we can have an arrangement of combined engines, arranged in series, in which the reciprocating engines utilise the energy of the steam only up to the limit of expansion suitable for a good efficiency, leaving to the turbine the duty of utilising the expansion down to condenser pressures, we shall then have an engine much superior, whatever be the speed of the ship, to one consisting exclusively of turbines or reciprocating engines.

Ever since 1900 we had foreseen the necessity of a combination of the two kinds of engines. At the meeting of this Institution of 1904* we described the arrangement installed, according to our ideas, by Messrs. Yarrow and Co., on board a small torpedo-boat. In this arrangement the reciprocating engines and the turbines were independent; by working the reciprocating engines only we could obtain very economical results at low speeds. But we must take account of the qualities as well as the faults of each engine; we have managed to gain some advantages, although we cannot eliminate all the faults.

In 1906 we fitted the French destroyer Voltigeur with an improved arrangement of engines. The power is distributed on three shafts (centre shaft reciprocating engine, with turbines on wing shafts). The engines are so designed that when going at full power the distribution is equal on these shafts. Up to a speed of 20 knots the reciprocating engines exhaust into the turbines, but above this speed the engines become independent. We would therefore have realised a perfect engine up to a speed of 20 knots, if the reciprocating engines and the turbines had been designed solely with the view to obtaining better results by working by stages; but, instead of this, they were designed more particularly with the object of obtaining the maximum efficiency at full power.

However this may be, the Voltigeur has undeniably demonstrated the superiority of the system, because below 20 knots the consumptions are slightly above those obtained in destroyers of the same class fitted with reciprocating engines. Above 20 knots, notwithstanding the presence of the reciprocating engines (which under such conditions are not advantageous), the consumptions remain less than those of all other destroyers, even with turbines only. This is due to the superior efficiency obtained with multicellular turbines. See Figs. 1 and 4, showing respectively the arrangement of machinery of the Voltigeur, and the comparative curves of consumption of the Voltigeur, Chasseur (with reaction turbines), and Carabinier (with reciprocating engines). In the author's opinion the best arrangement is the following:—

Combined Engines for Battleships and Cruisers.—The propulsive power is distributed on four shafts, each pair (port and starboard) being worked by an absolutely independent set of engines. In each set a reciprocating engine drives the wing-shaft, and exhausts into a turbine which drives the inner shaft.

The reciprocating engines and the turbines are designed to develop a power equally distributed on the four shafts when running at maximum speed. At cruising speeds the reciprocating engines develop much more power than the turbines. The reciprocating engines should naturally be able to run ahead and astern without engaging the turbines. This design includes an exhaust direct to the condenser; this exhaust opens at the moment when the normal exhaust to the turbines closes by means of two connected valves. These valves are operated automatically when starting, thus avoiding any error or loss of time. It appears unnecessary to introduce astern turbines on the centre shafts; but this could be arranged without much difficulty.

With such an arrangement the following advantages are obtained:—

1. *Maximum Speed.*—For the same weight of machinery, relatively to the propelling engines, there will be an increase of the maximum power from 15 to 20 per cent., which corresponds to an increase of speed from 5 to 7 per cent. of the maximum speed—say 1 to 1.5 knots for battleships intended for 20 knots.

* Paper read at the Jubilee meetings of the Institution of Naval Architects, July 5, 1911.

* Transactions of the Institution of Naval Architects, vol. xlvi., page 168; also ENGINEERING, vol. lxxvii., page 515.

2. *Cruising Speed.*—At this speed the consumption will probably be less than that of ships with reciprocating engines only, and it will not reach one-half of that with turbines. By comparison with the latter the radius of action will be doubled, or, if preferred, it may reduce the fuel supply in the same proportion.

3. *Manœuvring.*—When manœuvring in port it will be found that the arrangement of wing shafts driven by the reciprocating engines is a more favourable one than that of vessels with two or three propellers driven by reciprocating engines only. When manœuvring in squadrons, stations will be as easily kept as by other ships, because the regulation of speed can be adjusted by the operation of the stop-valve on the reciprocating engines.

Arrangement of Turbines for Scouts and Destroyers.

It will be readily understood that, although the distribution of the propelling machinery on four shafts does not present any inconvenience in large ships, it is difficult to achieve in the scout and destroyer classes.

If it is intended to apply the combined system in these small vessels, it will be necessary to adopt an arrangement with three shafts, similar to that of the Voltigeur, in which, at certain speeds, the reciprocating engine on the centre shaft will exhaust into the wing turbines; but in order to retain sufficient manœuvring qualities, it will be necessary to put astern turbines on the wing shafts, and a direct exhaust from the reciprocating engine to the condenser, so as to make this engine independent for manœuvring in harbour.

This arrangement may, perhaps, be thought complicated. To simplify it we may adopt the arrangement recently installed on the White Star Line vessels—two reciprocating engines driving the wing shafts, and both exhausting into the same turbine, placed on the centre shaft, and, when manœuvring, direct to the condenser. But the almost universal opinion is that it is wise to give up entirely the use of reciprocating engines for scouts and destroyers. These ships must be capable of developing at full power a considerable speed; they must, therefore, always be ready to pass from an ordinary cruising speed (14 to 16 knots) to very high speeds. On the other hand, the number of men composing the crew is limited through lack of accommodation, and it is necessary without greatly reducing their offensive value, to limit to the strictest minimum the numbers of the engine and boiler-room *personnel*.

The various conditions involve the use of engines and boilers of great flexibility and strength, and requiring the least manual effort; under these circumstances turbines and liquid fuel are essential. The difficulty is to have a good efficiency at ordinary cruising speeds. In order to overcome this, the cruising turbine, which utilises the expansion of the steam between the receiver pressure and the corresponding pressure at the exhaust into the high-pressure turbine, has been designed for the required speed. But the power developed by this cruising turbine being very small, it is not possible to make it work a propeller shaft by itself. It is, therefore, always placed on a shaft already driven by one of the main turbines. The result has been that the speed of rotation of this cruising turbine, which should be high in order to obtain a good efficiency, has been reduced by the speed of rotation of the main turbine, an obviously low speed, since it is proportional to that of the ship, and also because the cruising turbine does not come in except at moderate speeds of the ship. The efficiency, therefore, is always poor.

On the new French destroyers there are only two propelling-shafts, each shaft being driven by an independent turbine, as has been the practice since 1898, when the torpedo-boat No. 243 was used for experiments on the adoption of turbines for small ships. The results of these experiments were communicated by the author to this Institution in 1904.

The old cruising turbines, high-pressure and low-pressure, have been fitted in the same casing, end to end, thus obtaining all the advantage of great simplicity; but it is evident that the "cruising" part of these large turbines cannot give better results than the cruising turbines of engines arranged in separate groups. To avoid these inconveniences, and the use of toothed-wheel gears or electric motors, we have proposed the follow-arrangement, in which the high-pressure turbine maintains constantly at low-vessel speeds a relatively high velocity of rotation, and, in consequence, a higher efficiency.

Arrangement of Turbines.

The ship is propelled by three screws; each shaft is driven by a turbine; only the two-wing turbines being arranged for going astern (see Fig. 2, page 31). The centre turbine C is fitted with a steam inlet at the forward end G and with a by-pass H. The exhaust of the turbine C is connected with pipes I, I′ to the inlets L, L′ forward of the turbines A and B, and also by pipes K, K′ to some points N, N′ farther aft, in the parts of the distributers of these turbines; these have further an inlet of live steam forward through the pipes O, O′. All these pipes are fitted with valves.

When cruising at 15 knots, for example, the valves M, M′, P and P′ being shut, the turbine C receives steam through G and exhausts into the forward ends of the turbines A and B, which receive no other steam. If the speed has to be increased, we open the by-pass H; the connections of the turbine C with A and B remaining the same. For higher speeds, steam will be admitted through O or O′ into one of the turbines A or B, or both, if necessary; but, to avoid having compression at the exhaust of the turbine C, the exhaust is let out forward at N, N′ in the turbines A and B; when the valve M opens, it must at the same time close the valve J. In these conditions the live steam, after having worked in the first wheels of the turbines A and B, mixes with the steam exhausting from C, and the whole works in the last wheels.*

Thanks to this arrangement, the turbine C always works at great speed, but the power developed on the three shafts will not be equally distributed, as at low speeds the centre shaft develops relatively more power than at high speeds. If, for example, the power produced at a moderate speed on the shaft F is 44 per cent. of the whole, and on each wing-shaft D and E 28 per cent., the proportion at high speed may become 16 per cent. on F and 42 per cent. on each shaft D and E. The variations of slip of the propellers correspond to these variations of power.

At low speeds, nearly all the power being on the centre shaft, the slip of its propeller is great, say, from 25 to 30 per cent., while the slip of the wing-propellers is small. The conditions will remain similar so long as the live steam is admitted to the centre turbine only. When live steam is admitted into the wing-turbines the work produced by the centre turbine increases very little, the increase of power being almost entirely due to the wing-propellers. Their slip increases at the same time as that of the centre screw decreases, and the speed of rotation of the latter rises far less quickly than that of the wing screws. The best results have thus been obtained—namely, that at ordinary cruising speed a centre turbine does duty as a cruising turbine, having a very high speed of rotation. While cruising, it is not necessary to have both condensers working. The exhaust of the turbines A and B can be advantageously connected by means of the pipe T, which is of ample section to maintain an even pressure between the two condensers. In this way, during a long run at low speed, we can economise the motive power necessary to work one of the sets of pumps.

The arrangement which has just been described is not more complicated than that which consists in putting two independent turbines on two shafts only. It has the advantage of being lighter and of entailing less steam consumption at cruising speeds. At high speeds it has the same advantages as the well-known systems of equally distributed power on three shafts, in which the centre shaft is driven by a high-pressure turbine, and the wing shafts by low-pressure turbines, which do not receive any other steam than the exhaust of the high-pressure.

The manœuvring qualities of the ship are increased principally for harbour work, where a great advantage is gained by the action of the centre propeller on the rudder; in fact, it is only necessary to steam ahead with the centre propeller, while the others are manœuvring ahead or astern, and to join the exhaust of the turbine C with any point of the pipe T. This extension of manœuvring qualities is all the more important, as, with the increase in length of destroyers, it becomes more and more difficult for them to enter and moor in a harbour without the aid of tugs.

Necessity for Careful Design of Propellers.

In the above description we have purposely left out the question of propellers, which requires particular attention. It will not be inappropriate to conclude this paper by an account of the method of calculation for propellers in those two particular cases. We shall confine ourselves to describing the difficulties.

For the arrangement of turbines only it is not sufficient to make a design suitable for one speed only. If, for example, we are only requiring to have the best efficiency at high speed, where the three shafts have about the same number of revolutions, the same design for the three propellers may be adopted. At low speeds, on the other hand, the centre turbine develops a power relatively greater than the others, and its propeller revolves faster than the wing ones; in order, therefore, to obtain a suitable efficiency for cruising speed, the centre propeller, generally smaller than the others, must be very carefully designed.

In the case of the combination arrangement with reciprocating engines and turbines, the former develop at low speeds a power relatively high in comparison to those developed by the turbines; this difference decreases in proportion to the increase of speed, and almost disappears at the maximum speed. The slip of the propellers of the reciprocating engines decreases when that of the turbines increases. In designing propellers these peculiarities must be taken into account, and also the difficulty of associating for the same work propellers whose pitches are very different.

The curves in Fig. 3, page 31, show the data obtained during the official trials of the Voltigeur, and they indicate the importance of the variation of slip. The slip of the propeller of the reciprocating engine increases up to a speed of 20 knots; because up to this speed nearly all the power is supplied by this engine, and also because of the influence of the stern wave, which on the measured mile where the trials were made became defined in the neighbourhood of 24 knots.

Above 20 knots, the turbines come into operation, and the slip of the propeller of the reciprocating engine decreases until it reaches a very small value at the maximum speed. Just the contrary happens with the slip of the wing propellers, which is zero at the start, and increases rapidly until it reaches 26 per cent. and 28 per cent. Notwithstanding this relatively high value for the slip of the wing propellers at the maximum speed, the efficiency of the machinery remains good, as is shown by the excellent results obtained at the trials. The Voltigeur has really obtained a speed of 31.4 knots instead of 28 knots required by the contract specification.

* This is exactly what happens in the Rateau land-turbines, compound type, a great number of which are working in factories.

Let us also point out the remarkable difference in the increase of slip of the wing propellers, although they are similar and symmetrical. This difference certainly arises in great part from the fact that the powers developed by the two wing turbines are not equal; also because, owing to the presence of the centre screw, the stream-lines of the water as it reaches the wing-propellers are not symmetrical.

THE MARINE STEAM-TURBINE FROM 1894 TO 1910.*

By the Hon. Sir Charles A. Parsons, K.C.B., D.Sc., LL.D., F.R.S., Vice-President.

The application of the steam-turbine to the propulsion of vessels was entertained as early as 1884, but its development was not seriously considered till 1892, when the economy of the condensing turbine as applied to driving dynamos had excelled that of the compound reciprocating engine for the same purpose.

A pioneer association, called the Marine Steam-Turbine Company, Limited, was formed in 1894, whose object was the investigation of the subject. The prospectus opened with the following paragraph:—

"The object of the company is to provide the necessary capital for efficiently and thoroughly testing the application of Mr. Parsons's well-known steam-turbine to the propulsion of vessels. If successful, it is believed that the new system will revolutionise the present method of utilising steam as a motive power, and also that it will enable much higher rates of speed to be attained than has hitherto been possible with the fastest vessels."

From the first it was obvious that the turbine was suitable to fast rather than to slow vessels, and, consequently, it was decided to commence by building an experimental vessel of the smallest size consistent with the possibility of attaining exceptional speed. This vessel, the Turbinia, 100 ft. in length, 9 ft. beam, 6 ft. in depth, and 42 tons displacement, after many alterations to her machinery, developed 2400 horse-power on trials, and attained a maximum speed of 34½ knots. The machinery and trials of the little vessel were fully dealt with in the report of Professor J. A. Ewing, F.R.S., to be found in the Appendix to the paper read before the members of the Institution in June of 1903.† The trials of the Turbinia threw some additional light on the phenomenon of cavitation previously observed by Sir John Thornycroft and Mr. Sydney Barnaby, and demonstrated the necessity for very wide blades, and a sufficiency of total area in the propellers of such vessels. It was also shown that propellers of relatively small diameter and high revolutions could be designed to approach very closely in efficiency to propellers of large diameter and normal revolutions. Further, the reconstruction of the turbines showed clearly the gain in weight and efficiency by subdividing the power over turbines in series on the steam on different shafts. The net results of these trials proved that turbine propelling machinery was more economical than reciprocating machinery for high-speed vessels.

At this stage the pioneer association was transferred to a new company, the Parsons Marine Steam-Turbine Company, Limited, for dealing with the system on commercial lines. The first order was in 1899 for a destroyer, the Viper, from the British Admiralty, Sir William White being then Director of Naval Construction. The principal dimensions were the same as the 30-knot type of that period, but the speeds guaranteed were 31 knots ahead and half full-speed revolutions astern. Her maximum speed during a one hour's special trial, but with approximately full weights on board, was 36.5 knots, and under contract conditions of coal consumption was 33.38 knots. The economy in coal consumption at high speeds was good and she fulfilled in every respect the contract conditions, but the results of cruising speeds showed the desirability of modifications in the turbines in future designs to improve the economy at cruising speeds, and in all subsequent war vessels cruising turbines or cruising elements have been added at the high-pressure end of the turbine installation. In some very recent vessels impulse elements, in others geared high-pressure turbines, are being employed for the same purpose. At about the same time as the Viper was ordered, Messrs. Sir W. G. Armstrong, Whitworth, and Co., Limited, placed an order for the machinery of another destroyer, the Cobra. The machinery of the Cobra was a duplicate of that fitted in the Viper. The Cobra on a three hours continuous run maintained the mean speed of 34.6 knots.

It was very early realised that the suitability of the turbine for steam of very low pressure, which had been proved by the high percentage of power realised in the low-pressure portion of land turbines, would find an important application in ships by working the turbine from the exhaust of reciprocating engines, but not until 1901 was the first combination vessel, the Velox, a 30-knot destroyer, laid down as a speculation by the Parsons Marine Steam-Turbine Company, Limited. Her main propelling machinery was nearly a duplicate of the Viper's, but in order to increase the economy at speeds below 13 knots, two triple-expansion engines of 150 horse-power each were coupled to the low-pressure turbine shafts through flexible and detachable clutch-couplings. At low speeds the reciprocators exhausted into the high-pressure turbines; at speeds above 13 knots the engines were uncoupled. The vessel was acquired by the Admiralty in 1903. The same year H.M.S. Eden, of practically the same dimensions as the Velox, was launched, and cruising

* Paper read at the Jubilee meetings of the Institution of Naval Architects, July 5, 1911.

† "The Steam-Turbine and its Application to the Propulsion of Vessels," by the Hon. C. A. Parsons. Read before the Institution of Naval Architects, June, 1903.

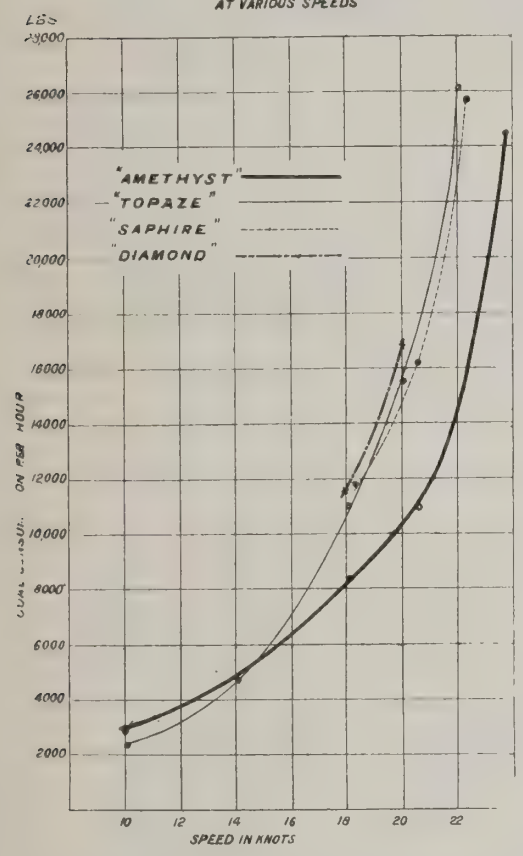
turbines in series were fitted in her instead of reciprocating engines.

The Admiralty carried out a series of comparative trials at cruising speeds with the Eden and Velox, and a sister vessel with reciprocating engines, of which the table below is a summary.

Water Consumption per Hour at various Cruising Speeds.

	Lbs. per hour.
At 11 knots—Velox, using piston engines exhausting into ordinary turbines	8,650
Eden, using cruising turbines exhausting into ordinary turbines	16,146
Piston-engined destroyer ...	14,892
At 13 knots—Velox, using high-speed turbines only	24,375
Eden, using cruising turbines exhausting into ordinary turbines	21,230
Piston-engined destroyer ...	18,140
At 15 knots—Velox, using high-speed turbines only	32,750
Eden, using low-pressure cruising turbines exhausting into ordinary turbines	28,000
Piston-engined destroyer ...	28,750
At 18 knots—Eden, using low-pressure cruising turbine exhausting into high-speed turbines	41,050
Piston-engined destroyer ...	45,645

FIG. 1. COAL CONSUMPTION PER HOUR AT VARIOUS SPEEDS



In 1902 the Admiralty placed the order for the third-class cruiser Amethyst with turbines, and for three sister vessels with reciprocating-engines of 10,000 horse-power. The turbine installation of the Amethyst was of the usual three-shaft arrangement, the high-pressure turbine driving the centre propeller, and the two low-pressure turbines in parallel on the steam driving the wing propellers, a high-pressure cruising turbine and an intermediate-pressure cruising turbine being also directly coupled through flexible claw couplings to the low-pressure turbine shafts; these latter were in series on the steam with the main high-pressure turbine. The trials of these vessels* conclusively proved the superiority of the turbine in water consumption (Fig. 1). At speeds of 15 knots, the water consumption of the turbine vessel was equal to that of the reciprocating vessels, and at higher speeds the superiority of the turbine was considerable, while at the designed speeds of 21¾ knots it reached 30 per cent., and at the maximum coal consumption allowed by the specification, the power developed, as estimated from the curve of resistance of the vessel, by the turbine vessel exceeded the power developed by the reciprocating vessel by 42 per cent. The maximum speed attained by the Amethyst was 23.6 knots as against 22.3 knots for her sister ships. The increased efficiency derived from the cruising turbines was very marked at low speeds, at some speeds 20 per cent. of the total power being developed by them.

Subsequent to the official trials arrangements were made for utilising the auxiliary exhaust in the turbines, when a further increase in economy was obtained.

The comparative trials of these vessels had a great influence upon the future of the turbine.

* See ENGINEERING, November 18, 1904.

As a general rule, the larger and faster the vessel, the more easy it had been to arrive at a satisfactory and profitable all-turbine solution as regards efficiency and first cost. Below the sea speed of 16 knots, the solution is not altogether favourable, and very few such vessels have been fitted. A slight lowering of the boundary of suitable speed exists in very large vessels, and also may be effected by the employment of the impulse principle at the high-pressure end, as more fully explained later.

This most important question of applying the turbine to lower-speed vessels has from the commencement received consideration, and one satisfactory solution appeared to lie in the combination system to which we shall further allude later. Another solution with a somewhat different scope has more recently been investigated; it is the use of double helical gearing of the De Laval class on a large scale for gearing the high-pressure portion only, or in some cases the whole of the turbines on to the screw shafting. Both of these solutions have given satisfactory results, but the reduction gearing appears to be the more important as applicable to vessels of all speeds. Both systems are described more fully later.

The first turbine battleship Dreadnought was laid down at Portsmouth in October, 1905. The primary contract for the whole of the machinery was placed with Vickers Sons and Maxim, Limited, the Parsons Marine Steam Turbine Company, Limited, being sub-contractors for the turbines. She has four shafts, two high-pressure and two low-pressure turbines, and two cruising turbines are coupled to the low-pressure turbine shafts. The astern turbines consist of a high-pressure astern portion in a separate casing on the high-pressure ahead shaft, in series with a low-pressure astern portion incorporated in the main low-pressure-turbine casing. The cruising turbines are in parallel, and not in series, on the steam as in the Amethyst; the high-pressure, low-pressure, cruising, and astern turbines comprise one propelling unit on each side of the vessel.

We may quote a summary of the advantages of the system, the reasons given by the First Lord of the British Admiralty for the adoption of the Parsons turbine in the Dreadnought and succeeding ships as determined by a committee on naval design:—"The question of the best type of propelling machinery to be fitted was most thoroughly considered. While recognising that the steam-turbine system of propulsion has, at present, some disadvantages, yet it was determined to adopt it because of the saving in weight and reduction in number of working parts, and reduced liability to breakdown, its smooth working, ease of manipulation, saving in coal consumption at high powers, and hence boiler-room space, and saving in engine-room complement; and also because of the increased protection provided for with this system, due to engines being lower in the ship—advantages which more than counterbalance the disadvantages. There was no difficulty in arriving at a decision to adopt turbine propulsion from the point of view of sea-going speed only. The point that chiefly occupied the committee was the question of providing sufficient stopping and turning power for purposes of quick and easy manœuvring. Trials were carried out between the sister vessels Eden and Waveney, and the Amethyst and Sapphire, one of each class fitted with reciprocating and the other with turbine

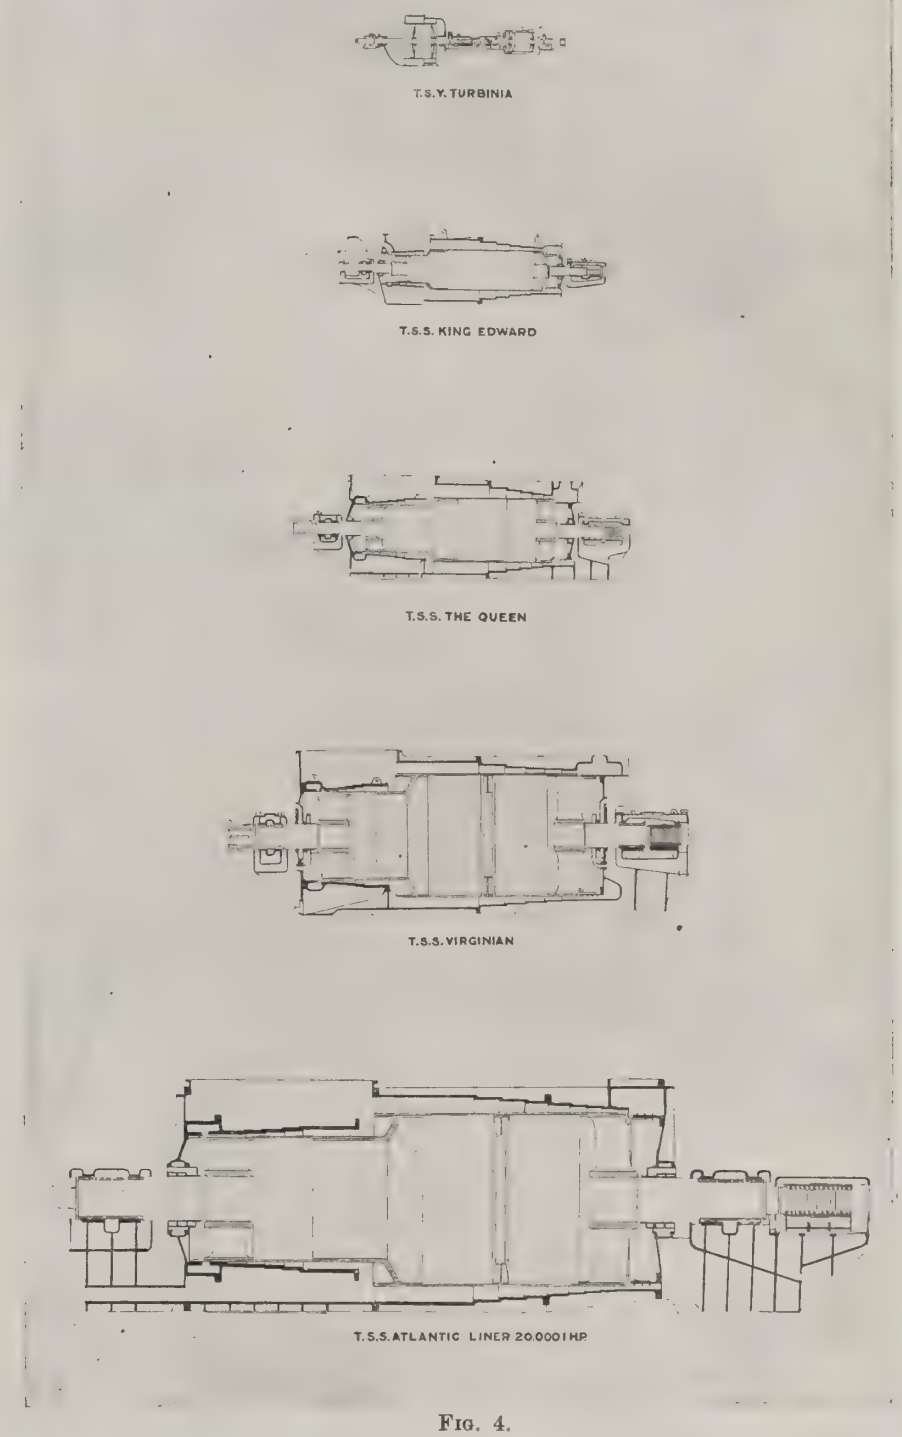


FIG. 4.

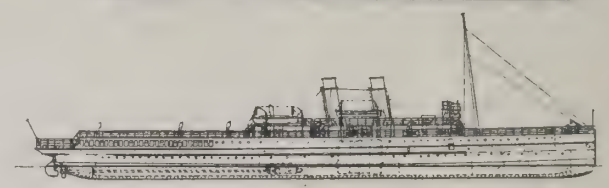
THE MARINE STEAM-TURBINE FROM 1894 TO 1910.

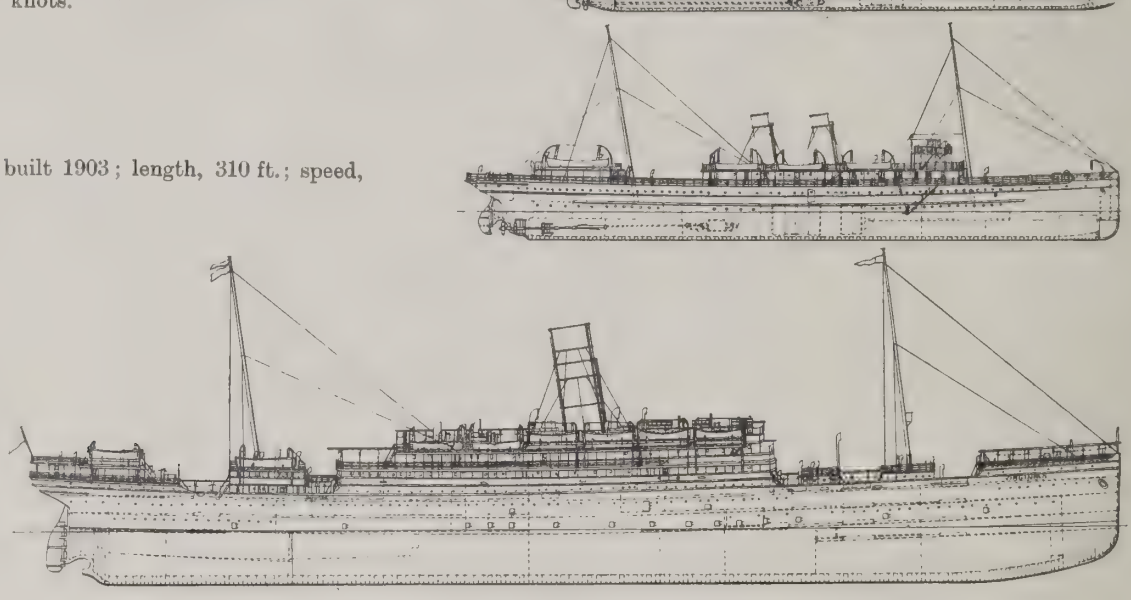
"Turbinia:" built 1894; length, 100 ft.; displacement, 44½ tons; horse-power, 2300; speed, 32¾ knots.

"King Edward:" built 1901; length, 250 ft.; displacement, 650 tons; shaft horse-power (estimated), 3500; speed, 20.48 knots.

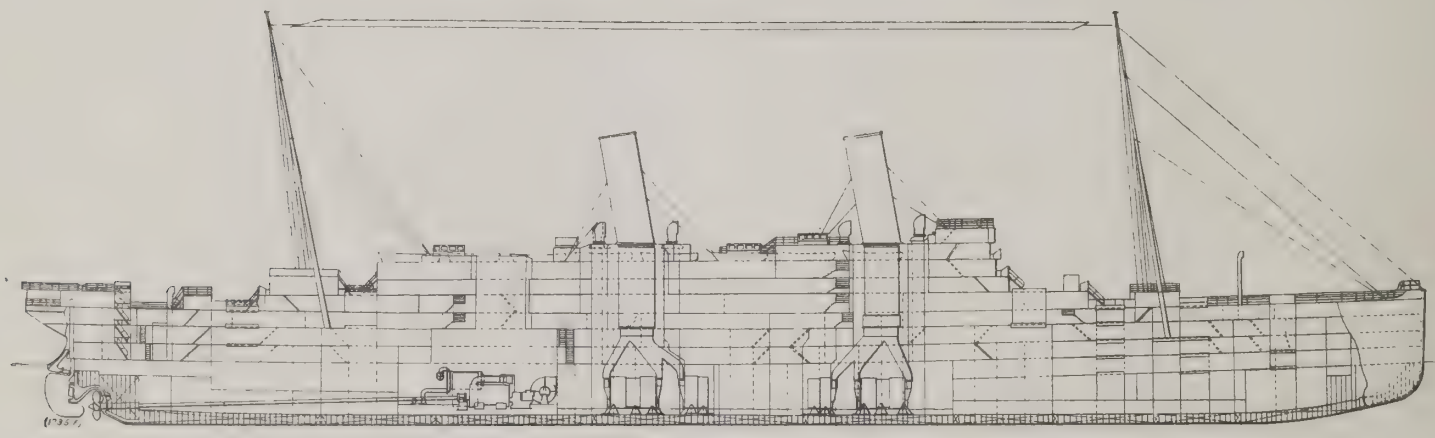
"Queen Alexandra:" built 1902; length, 270 ft.; displacement, 750 tons; shaft horse-power (estimated), 4000; speed, 21.625 knots.



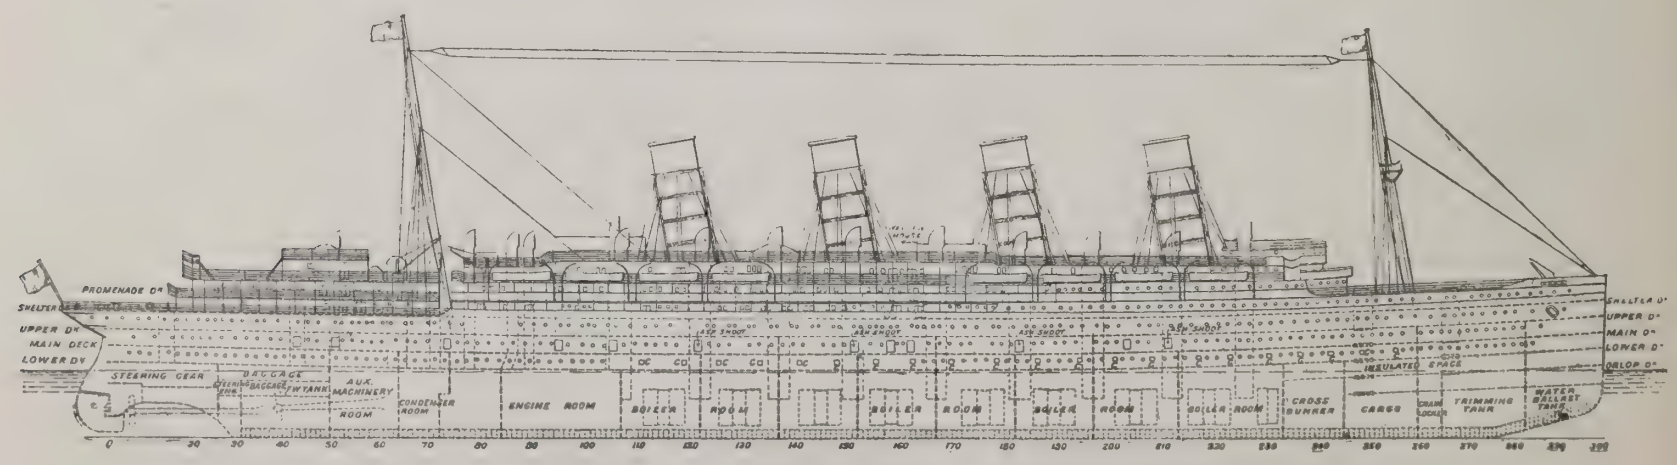
"The Queen:" built 1903; length, 310 ft.; speed, 21.76 knots.



"Virginian," built 1905; length, 530 ft.; displacement, 13,000 tons; estimated shaft horse-power, 12,000; speed, 19.1 knots.



"Carmania:" built 1905; length, 675 ft.; displacement, 30,000 tons; shaft horse-power, 21,000; speed, 20½ knots.



"Mauretania" and "Lusitania:" built 1907; length, 785 ft.; displacement, 40,000 tons; shaft horse-power, 74,000; speed, 26 knots.

FIG. 5. DIAGRAM SHOWING GROWTH IN SIZE OF TURBINE-PROPELLED MERCHANT SHIPS.

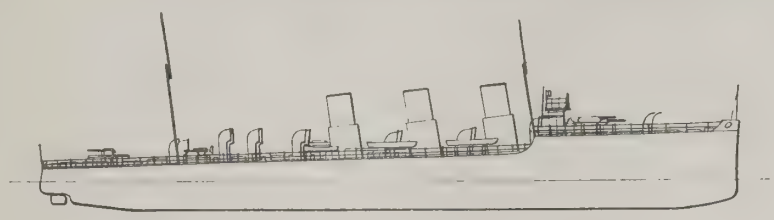
THE MARINE STEAM-TURBINE.

"Turbinia:" built 1894; length, 100 ft.; displacement, 44½ tons; horse-power, 2300; speed, 32¾ knots.

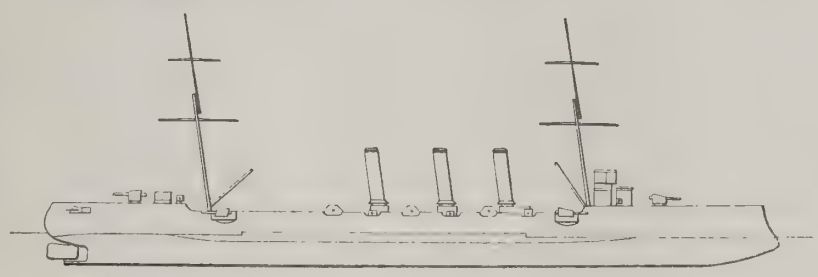
H.M. torpedo-boat destroyer "Velox:" built 1902; length, 210 ft.; displacement, 420 tons; shaft horse-power, 8000; speed, 27.12 knots.

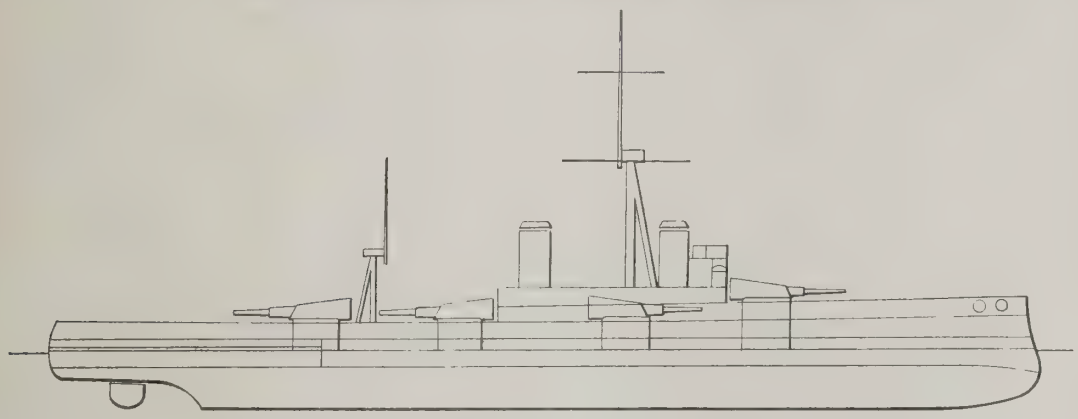
H.M. torpedo-boat destroyer "Eden:" built 1903; length, 220 ft.; displacement, 540 tons; shaft horse-power, 7000; speed, 26.22 knots.

H.M. torpedo-boat destroyer "Swift:" built 1908; length, 345 ft.; displacement, 2170 tons; shaft horse-power, 35,000; speed, 35.3 knots.

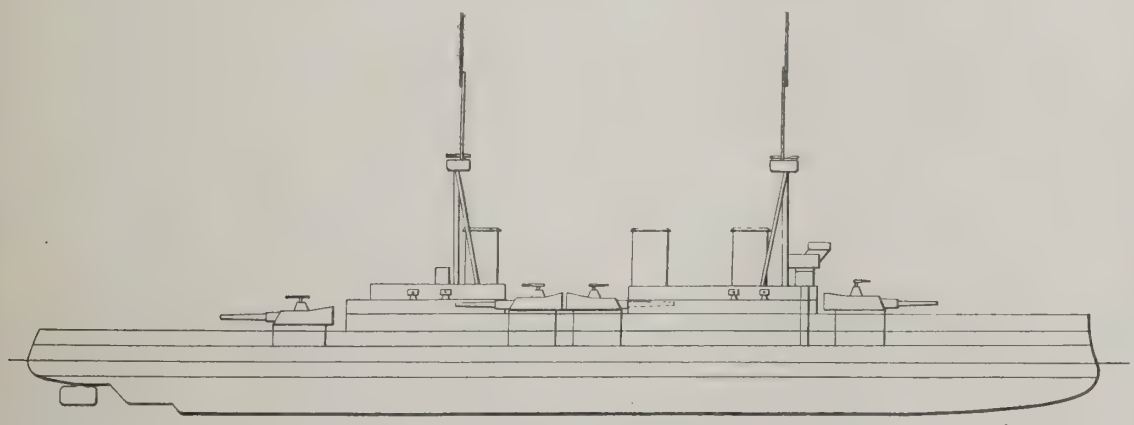


H.M. 3rd-class cruiser "Amethyst:" built 1905; length, 360 ft.; displacement, 3000 tons; shaft horse-power (estimated), 14,200; speed, 23.63 knots.





H.M. Battleship "Dreadnought:" built 1906; length, 490 ft.; displacement, 17,900 tons; shaft horse-power, 24,712; speed, 21.25 knots.



H.M. Armoured Cruiser "Invincible:" built 1908; length, 530 ft.; displacement, 17,250 tons; shaft horse-power, 42,000; speed, 26 knots.

FIG. 6. DIAGRAM SHOWING GROWTH IN SIZE BETWEEN 1894 AND 1908 OF TURBINE-PROPELLED WARSHIPS.

engines; experiments were also carried out at the Admiralty experimental works at Haslar, and it was considered that all requirements promise to be fully met by the adoption of suitable turbine machinery, and that the manœuvring capabilities of the ship when in company of a fleet, or when working in narrow waters, will be quite satisfactory.

Sir Henry Oram, the Engineer-in-Chief of the Fleet, in his address as President of the Junior Institution of Engineers,* stated that at full power the steam consumption of the Dreadnought was 13.48 lb. per shaft horse-power per hour, while in the succeeding battleships of the class it averaged 13.01 lb., and in the three cruisers of the Invincible class 12.03 lb. With reciprocating engines nearly 16 lb. would be a fair average, and it thus follows that a great reduction in boiler weights was permissible.

* See ENGINEERING, vol. lxxxviii., page 703.

Again the high efficiency of the low-pressure turbine made it well worth while to pass the exhaust steam from the auxiliary engines to this turbine instead of to the condenser. Indeed, the exhaust steam in some battleships has been proved to be alone sufficient to drive the vessel at a speed of 5 to 6 knots.

The coal consumption at full power of the three 26-knot armoured cruisers of the Invincible class ranged from 1.2 lb. to 1.7 lb. per shaft horse-power per hour, the average for the three ships being 1.47 lb. per shaft horse-power. In the three cruisers of the Minotaur class, with piston engines, it was 1.8 lb., and in the six cruisers of the Duke of Edinburgh or Warrior class 2.1 lb. per indicated horse-power per hour. On the thirty hours' endurance trial at 70 per cent. of the total power, the turbines also proved more efficient, although the advantage was not so marked. At one-fifth power the coal consumption of the three Invincible cruisers averaged 2.4 lb. per shaft horse-power per hour, as compared with 1.87 lb. per indicated horse-power per hour in the Minotaurs and 2.05 lb. in the Duke of Edinburgh cruisers.

In the mercantile marine the first vessel to be fitted with turbines was the Clyde passenger steamer, King Edward, built to the joint ownership of Captain John Williamson, Messrs. Denny, of Dumbarton, and of the Parsons Marine Steam-Turbine Company, Limited. Her length is 250 ft., and, with 3500 horse-power, she attained a speed of 20.48 knots. Her success led to the construction of a second vessel for the Clyde passenger traffic in 1903, and in the same year the Queen was built for the Dover and Calais route. All these vessels have three shafts, the high-pressure turbine in the centre exhausting into two low-pressure turbines on the wing shafts. Thus, by 1904, two of the most suitable fields for the marine turbine had been entered, namely, for vessels of war and cross-channel and passenger service, and, by 1905, the turbine was being adopted for nearly all new cross-channel steamers of high speed built in this country, and about a year later by the British Admiralty for all new construction.

The application to large liners remained as yet untouched. The first vessels to be fitted with turbines for Transatlantic service were ordered by the Allan line, viz., the Victorian and Virginian. This marked a notable step in advance in the application of the new system to ocean-going ships of high speed. At this juncture the late Lord Inverclyde appointed a commission of experts to investigate the suitability of the turbine for two express Cunarders for the New York route. After most careful consideration of all data then available, and in view of much additional experimental research conducted by the committee, as well as tests on large land turbines, and on existing turbine vessels, the committee unanimously recommended turbines in preference to reciprocating engines for the Mauretania and Lusitania of 70,000 horse-power and 24½ knots sea speed. The performance of these vessels has justified the decision; a mean speed of 26 knots has been maintained in favourable weather across the Atlantic, and an average speed of 25½ knots has been maintained on many successive voyages. This step completed the entry of the turbine into all classes of fast vessels for which it was at the time deemed suitable, and its adoption for fast vessels has since been almost universal.

In 1904 the general policy of granting licences on easy terms was decided upon by the Parsons Marine Steam-Turbine Company, and by the end of 1905 a large number of shipbuilding and engineering firms had acquired marine licences, the number having considerably increased up to the end of 1910. It is now clear that the broad policy then adopted has been conducive to the exceptionally rapid adoption of the turbine. Turbines of the Parsons type are now being built in the principal engineering works of France, Germany, Austria, Italy, Russia, Spain, Belgium, Sweden, and Denmark, as well as in Japan and the United States of America. The curve of horse-power (Fig. 2, page 36) completed and on order each year up to the end of 1910 shows the development which has taken place since the introduction.

Since the construction of the turbines of the Turbinia in 1897, which were in series on the steam and on three shafts, there has been no very notable increase in economy in steam per shaft horse-power, excepting that due to size and consequent reduction of leakage and steam friction losses, the reason being that the turbines of the Turbinia were designed with as high a velocity ratio as has been found compatible with weight and space, and that her condensers were of ample size.

In marine turbine design the chief governing factors are weight and cost dependent on a limited surface speed of turbine, which is governed by the maximum speed of revolution allowed by the propeller, and from the commencement a judicious compromise has been arrived at between turbine and propeller. Such limitations will, however, be materially reduced, should geared turbines come into use, and higher coefficients of turbine efficiency would then become possible and compatible with moderate first cost and weight; the question of propeller efficiency would be more easily dealt with, and the gain in total propulsive efficiency thereby would be substantial.

TYPES OF TURBINE.

There are four principal types of turbine now in use for marine work:—

1. The compound class, introduced in 1894 in the

Turbinia, in which there are a very large number of turbines on drums in series, with small pressure-drops at each turbine and low steam velocities. Generally the guide-vanes are identical with the moving vanes, each taking half the pressure-drop, but occasionally the moving vanes are formed like cups or buckets, and then the whole pressure-drop is taken on the guides. This class comprises, say, 90 per cent. of all marine-turbines at the present time.

2. The multiple impulse compounded or Curtis type introduced in the Revolution and in the Creole in 1904 and the Salem in 1906. This system differs radically from the compound class, in that there are comparatively few stages, large pressure-drops take place at the guides or nozzles, and the high steam velocities generated are absorbed in a sinuous course between several rows of moving and fixed buckets.

3. A combination of the two types (1) and (2), in which the earlier part of the expansion is taken by the impulse type and the low-pressure part by the compound type. The impulse Parsons, with one impulse-wheel, the Brown-Curtis with several impulse-wheels, the A.E.G. turbines and others are instances of this type.

FIG. 2.

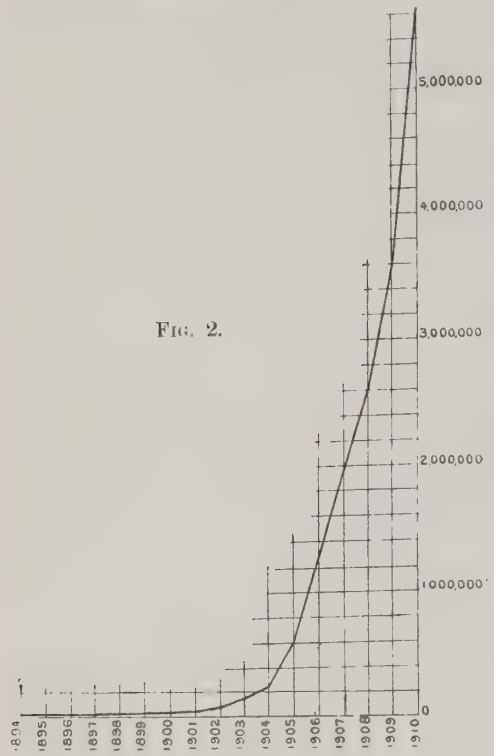


FIG. 2.—Diagram showing total horse-power of Parsons' steam-turbines applied to marine propulsion, completed and under construction each year from 1894 to December, 1910.

4. The multiple or compound De Laval wheel type, in which there are a large number of simple bucket wheels working in separate chambers. The pressure drops are moderate, and take place wholly in the guides, which form the passage-way from chamber to chamber. The Rateau, the Zoelly, the Bergman, and others are instances.

After type (1), type (3) has received the largest use in marine work, more especially in Germany. Each class or type has its advantages and disadvantages, but within the scope of the paper it is not possible to do more than make a few general remarks.

The compound class has low steam velocities, and there is no cutting action of the blades by the steam. Its efficiency, when the blades are of reasonable length, and leakage consequently small, is the highest, as the skin friction losses in the blades and of the moving drums and dummy pistons are small. On the other hand, when the design necessitates very short blades, as may occur at the high-pressure end, then the efficiency is reduced by leakage.

The multiple impulse type has a lower efficiency because of the skin friction losses of the steam circling through the blades at high velocity, and from the spilling of the steam from the buckets. On the other hand, it is less subject to leakage than the compound, and in the case of the first wheel of a series there is no leakage at all, and the only losses are skin friction and spilling. One impulse wheel, therefore, is a good substitute in certain cases for the initial stage of the compound, and in this design no diaphragms or shaft packings are required. The advantage of replacing several initial stages of the compound by several multiple impulse wheels in chambers separated by diaphragms and shaft packings, is somewhat questionable, and on it a difference of opinion exists.

Class (4) has small leakage losses, but involves relatively more skin friction loss from the large surface of the many discs revolving in the steam, which in the initial chambers is of high density.

THE COMBINATION SYSTEM.*

The Velox, in 1901, as has been stated, was the first combination vessel. The system was described and advocated by me in my Presidential Address of the Institute of Marine Engineers, in January, 1905. The Otaki, of 464 ft. length, 9900 tons dead-weight capacity, built and engined by Messrs. Denny, of Dumbarton, in 1908, for the New Zealand Shipping Company, was the second; the sister vessels, the Orari and Opawa, were fitted with triple-expansion engines. The diagram (Fig. 3), which is taken from a paper by Engineer-Commander W. McK. Wisnom, R.N., before the Institution of Engineers and Shipbuilders in Scotland, vol. liii., page 279, gives the comparative results.

About the same time the Laurentic and Megantic were laid down by Messrs. Harland and Wolff, for the Canadian service. They are 565 ft. in length, and about 20,000 tons displacement. The first was fitted with triple-expansion engines driving the side screws, and a low-pressure turbine driving the centre screw. The latter vessel was fitted with the usual quadruple expansion engines and twin screws. In service it is stated that the combination vessel consumes 12 to 14 per cent. less coal than the sister vessel.

In 1909 Messrs. Harland and Wolff commenced the Olympic and Titanic, of 882 ft. 9 in. in length, and about 60,000 tons displacement, the arrangement of combination machinery being similar to that of the Laurentic, with a collective horse-power of 30,000, the designed sea speed is 21 knots. The same firm is fitting the combination system in the Demosthenes, of 19,500 tons displacement, to steam 13 knots, being built for Messrs. George Thompson and Co., Limited, and also in a large ship for the Royal Mail Steam Packet Company's service to the South American republics.

The Orient Line ordered combination machinery for the Orama, laid down in 1910 for their Australian mail service. The vessel is 550 ft. long, and of about 18,000 tons displacement, and is being constructed and engined by Messrs. John Brown and Co., Limited, Clydebank. All these ships have triple-screws, each reciprocating engine driving a wing-shaft and propeller, while the turbine, taking the exhaust steam from both engines, works the centre screw. This arrangement has the advantage that, in manœuvring and for going astern, the piston engines only are used, and thus there is no need for an astern turbine. At St. Nazaire, in France, an intermediate liner, the Rochambeau, is being built, and she has four shafts, the reciprocating engines driving the inner shafts and the turbines the wing propellers.

REDUCTION GEARING BETWEEN THE TURBINE AND THE PROPELLER.*

Several forms of gearing have been proposed. Electrical gearing was fitted, I believe, by the Heilmann Company, in a small vessel about thirteen years ago, but little is known of the results. Continuous-current generators and motors were originally proposed, but of late years some form of alternating-current transmission has been preferred by the advocates of the system.

Within the last few months a 50-ft. vessel has been fitted by Mr. Henry Mavor, of Glasgow, with his form of alternating-current generator and motor, and a suction-gas engine directly coupled to the generator. A quick reversal or graduation of speed of the propellers can be effected without altering the speed of the engine by this method. The efficiency of the electrical transmission is said to reach 88 per cent. The same means of transmission is applicable to the steam turbine.

An hydraulic transmission-gear has been developed by Mr. Föttinger, and has been fitted in two small vessels. The efficiency of transmission is said to reach 86 per cent.

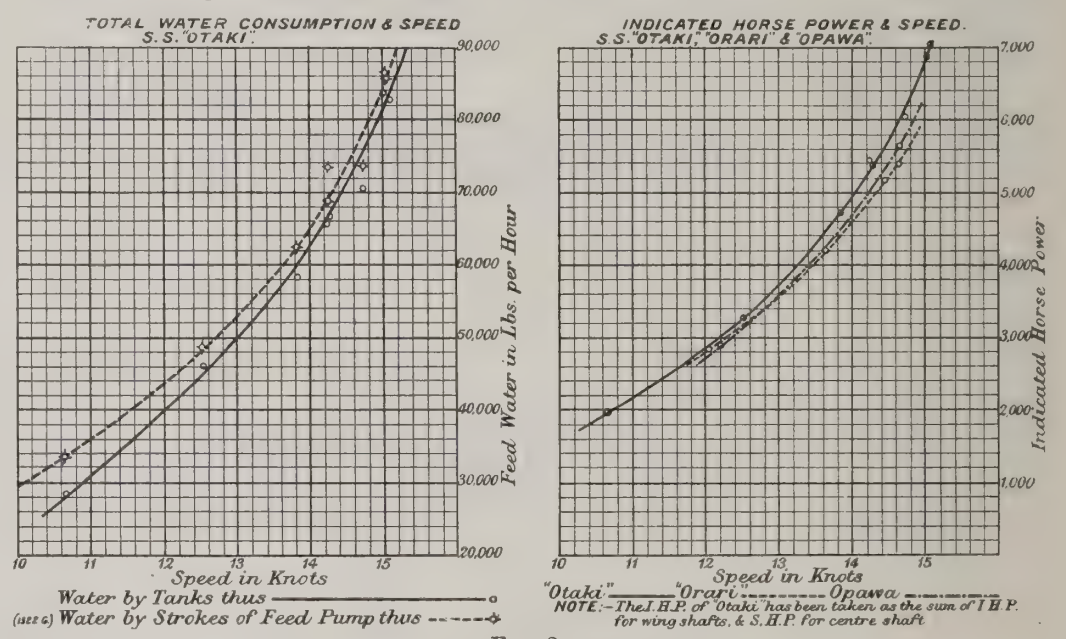

FIG. 3.

The first application of geared turbines was made by the Parsons Marine Steam-Turbine Company in a 22-ft. launch in 1897. Double helical reduction gear between the turbine and the propeller has so recently been the subject of papers before this Institution, that it is unnecessary to say more than that it promises to be an important factor in many marine turbine installations in the future. With an efficiency of over 98 per cent., and a remarkable absence of wear, it will add considerably to the efficiency of turbine installations even in fast vessels, and, what is of greater importance, it makes the turbine applicable to all classes of vessels. The London and South-Western Railway Company have recently decided to fit two new steamers of 5000 horse-power and 20 knots speed with geared turbines. They will have twin-screws, and a high-pressure and a low-pressure turbine will be geared on to each screw shaft, similarly to the arrangement in the Vespasian.

Although the manufacture of land turbines began to be general on the Continent in 1900, it was not till 1902 that the first turbine-propelled vessel was ordered by the French Admiralty, a torpedo boat, length 130 ft., 94 tons displacement, and 26½ knots speed. She had three shafts, and the turbines, which were built by the Parsons Marine Steam-Turbine Company, at Wallsend-on-Tyne, were in series similar to those of the Turbinia, but with one cruising turbine coupled to the low-pressure turbine which drives the centre shaft, and a reversing turbine in the low-pressure casing.

In 1906 a second vessel, the Chasseur, was ordered, a destroyer of 210 ft. length, 458 tons displacement, 9000 horse-power, and 30.4 knots speed. Her arrangement of turbines differed from that of British destroyers, inasmuch as only one cruising turbine was fitted, and the machinery was arranged in two compartments, one abaft the other. In 1906 it was decided that the six battleships of the Danton class should be fitted with reaction turbines. The Danton was the first to be completed. She was built and engined by the La Seyne Works, of the Forges et Chantier Company. She is 475 ft. length, 84 ft. 7 in. beam, and 18,374 tons displacement. The designed speed was 19.25 knots, with 22,500 shaft horse-power, but on her contract trial she maintained 20.66 knots in choppy seas, and during part of the run exceeded 21 knots. Similar results have been obtained in sister ships.

Two more battleships were laid down in 1910 of 542 ft. length, 23,467 tons displacement, and 20 knots designed speed with 28,000 shaft horse-power. Since 1908 the French Admiralty have ordered no vessels with reciprocating engines. In 1909 a change was made in destroyer practice, all the boats being fitted with twin-screws, and in some the combination impulse reaction turbines with an impulse-wheel followed by reaction blading.

The first marine turbines fitted in a merchant steamship built in France were made in 1908 at the works of Cie Electro-Mécanique for the Mediterranean steamer Charles Roux, of 9000 horse-power and 19 knots speed. The Transatlantic liner France, of 688 ft. length, 25,460 tons displacement, and 23 knots speed, with steam turbines of 40,000 shaft horse-power, is now approaching completion. The Newhaven for the Newhaven and Dieppe service has been completed, and has averaged 23.85 knots, mean of two cross-channel trips. There is also building in France the intermediate liner Rochambeau. In Germany the marine turbine was first introduced into the torpedo-boat destroyer S 125, ordered towards the end of 1902. This vessel was one of the class of six boats ordered that year, the remaining boats having the ordinary type of reciprocating engines. In the following year the cruiser Lübeck was ordered by the German Admiralty to be fitted with Parsons turbines. A series of comparative trials were made with this vessel and a sister vessel, the Hamburg, fitted with reciprocating engines. The results obtained on service of the destroyer S. 125 and the cruiser Lübeck, as compared with those of the sister vessels fitted with reciprocating engines, were conclusive in favour of the turbine boats. The destroyer S 125 wa

* "The Combination System of Reciprocating Engines and Steam-Turbines," by the Hon. C. A. Parsons and Mr. R. J. Walker, before the Institution of Naval Architects, April 9, 1908.

* Paper on "The Application of the Marine Steam-Turbine and Mechanical Gearing to Merchant Ships," by the Hon. C. A. Parsons, before the Institution of Naval Architects, March 18, 1910, and "Twelve Months' Experience with Geared Turbines in the Cargo Steamer Vespasian," by the Hon. C. A. Parsons and Mr. R. J. Walker, before the Institution of Naval Architects, April 5, 1911.

fitted with the ordinary three-shaft arrangement of turbines, and also cruising turbines.

The turbines of the cruiser Lübeck were arranged on four shafts, each of which in the first trial carried two screw propellers. The shafts on each side of the ship are driven by a high-pressure and a low-pressure turbine. Cruising turbines arranged in series were also fitted. An independent high-pressure reversing turbine was fitted to each shaft. This latter arrangement has not since been repeated; such reversing turbines are now always arranged and worked in series.

Following shortly on the completion of the S 125, the new destroyer G 137 was commenced. This vessel was the most powerful destroyer built up to that time in Germany, the turbine machinery arranged in two engine-rooms being nearly double the power of the S 125. Designed for a speed of 30 knots, she attained 33.08 knots on a three hours' run. All destroyers subsequent to the trials of G 137 have been fitted with turbines, and in some of the later vessels twin screws have been adopted. Meanwhile, following the Lübeck, the protected cruisers Stettin, Dresden, Augsburg, and Ersatz Condor, were equipped with turbine engines.

In 1907 the large armoured cruiser Von der Tann was ordered to be built by Messrs. Blohm and Voss, of Hamburg, and she has been followed by the Moltke, Goeben, and cruiser J. All these great cruisers are fitted with turbines of the Parsons type, with a four-shaft arrangement similar to that adopted in recent British armoured cruisers. On her contract trials the Von der Tann developed about 80,000 horse-power, and attained a maximum speed of 28 knots.

Reciprocating engines were fitted in German battleships until 1909, when two vessels were ordered with steam-turbines of the Parsons type. These vessels will be completed next year, and their trials will be of much interest, although their power and speed are inferior to those of the armoured cruisers. It is understood that later battleships of 1910 and 1911 programmes are also to be fitted with turbines. The Imperator, a new large liner building for the Hamburg-Amerika line by the Hamburg Yard of the Vulcan, has Parsons (series) turbines, and Blohm and Voss are contracting for a second similar vessel for the same owners.

The first vessel to be fitted with Parsons turbines in the United States was the passenger steamer Governor Cobb. This vessel, built by the W. and A. Fletcher Company in 1905, is 290 ft. long, 2900 tons displacement, and 20.5 knots speed. The arrangement of machinery is identical with that adopted in the King Edward. Following the Governor Cobb, the next vessels to be designed with turbines for passenger service were the Yale and Harvard, of 4600 tons displacement, 10,000 horse-power, and 22½ knots speed; the Old Colony, of 3800 tons displacement and 20 knots speed, and the Camden and Belfast, of 1820 tons displacement, with a speed of 19 and 18½ knots respectively. At about the same time as the Governor Cobb was ordered, the United States Government placed the contract for the three scout cruisers Birmingham, with twin-screw reciprocating engines; Salem, with Curtis turbines, and the Chester, with Parsons turbines. The turbines of the Salem were arranged on two shafts, and in the Chester on four shafts in two engine-rooms, one abaft the other.

Up to the time when the scout cruisers were ordered the Curtis type of turbine had been fitted only to a small vessel named the Revolution, and to the mercantile steamship Creole. It is understood that the turbines have since been removed from both these vessels. The Salem was therefore regarded as an experimental vessel, so far as the Curtis turbines were concerned, whereas the Chester with Parsons turbines represented one of a series of cruisers of which the Amethyst was the pioneer.

Cruising turbines in series were fitted in the Chester, one on each of the low-pressure turbine shafts. Astern turbines were only fitted on two of the four shafts, being incorporated in the exhaust casings of the low-pressure turbines. The comparative trials of these three vessels have from time to time been reviewed in leading technical journals. The contract speed was 24 knots, and on the full-power trial the Birmingham attained 24.325 knots, the Salem 25.947 knots, and the Chester 26.52 knots.

In 1907, before the competitive trials of the scout cruisers were completed, the battleship North Dakota was ordered by the Navy Department from the Fore River Company, and it was decided to fit her with Curtis turbines of about 25,000 horse-power, her sister ship the Delaware being fitted with reciprocating engines. These two vessels were completed last year, and have been subjected to competitive trials both under contract conditions and on sea service.

Early in 1909, on the conclusion of the tests of the scout cruisers, the Navy Department decided to adopt the Parsons type of turbines for the new battleships now building—viz.: Utah, Florida, of the 1908 programme, of 21,800 tons displacement and 28,000 horse-power, and later on the Wyoming and Arkansas of 26,000 tons displacement and 30,000 horse-power. The trials of the Utah will take place shortly, and the future policy of the Navy Department in regard to battleships will doubtless be decided in view of the results obtained. Meantime, it has been decided to fit reciprocating engines in one battleship now building. Since 1907 all contracts for new destroyers awarded by the United States Navy Department have specified turbine engines.

In Japan four merchant vessels were fitted with Parsons turbines in 1908. Two of these, the Tenyo Maru and Chiyo Maru, were built at the Mitsu Bishi Dockyard at Nagasaki, the turbines for which were constructed by the Parsons Marine Steam-Turbine Company, Limited. Two others, the Hirafu Maru and the Tamura Maru were built and engined by Messrs. Denny, of Dumbarton.

The volunteer steamers Sakura Maru and Umegaka Maru were built and engined with Parsons turbines in 1908-1909 by the Mitsu Bishi Company. The Mogami, a despatch vessel for the Imperial Japanese Navy, was completed in the summer of 1908. There are also at present under construction for the Imperial Japanese Navy two cruisers and two high-speed destroyers with turbines of that type.

For larger warships the Japanese Admiralty have adopted Curtis turbines in the Ibuki armoured cruiser and Aki battleship, both of which were launched in 1907. Both these vessels have been tried and the results published. Subsequently it has been decided to adopt the Parsons type in the large armoured cruiser now building for the Japanese Navy by Messrs. Vickers, and in three sister ships to be built in Japan. The Japanese Admiralty has also taken a licence for the manufacture of the Parsons steam-turbines in the national dockyards.

In Italy the cruiser San Marco is the first turbine ship for the Royal Italian Navy. On her trials she attained a speed of 23.7 knots, being nearly two knots in excess of the speed attained by a sister vessel, the San Georgio, fitted with reciprocating machinery. The Città di Catania and the Città di Palermo, two passenger vessels of 3500 tons displacement and 23 knots speed, were recently put on service for the Italian State Railway Company. At the present time there are under construction in Italy for the Royal Italian Navy, Parsons turbines for four battleships, and several other vessels.

All the principal navies of the world are now following the lead of the British Admiralty. In Russia four large battleships of high power are under construction. In Austria the scout Admiral Spaun was ordered in 1907, and on her trials she attained a speed of 27.07 knots, with 25,000 shaft-horse-power. Three battleships and 12 torpedo-boats are now on order in Austria with Parsons turbines, some of which are now building. Sweden and Denmark have recently ordered their first turbines for warships:—a 7000 horse-power set for a 21-knot cruiser in the case of Sweden, and engines of 4000 horse-power for some twin-screw torpedo-boats in the case of Denmark. In Spain three battleships, three destroyers, and ten torpedo-boats, comprising the important recent naval programme of this navy, are to be fitted with turbine machinery. Portugal is having one destroyer built. Brazil has now two turbine scout cruisers, Bahia and Rio Grande do Sul, on service. These two vessels on trial averaged a speed of 27¼ knots. The Argentine Government are adopting turbines for their four new destroyers, now being built by Messrs. Cammell Laird and Co. China is having three small cruisers built. Belgium does not possess a war navy, but three turbine vessels have been built for the Government passenger line, the Princesse Elisabeth, of a speed of 24.03 knots in 1905, and the two vessels Jan Breydel and Pieter de Coninck, of speeds 24.3 knots. Peru possesses two passenger steamers, Huallaga and Ucayali, of 6000 tons displacement and 19 knots speed. The British Colonies of Canada, Australia, and New Zealand are having various classes of war vessels fitted with the turbine system.

Fig. 4, page 33, illustrates the progressive increase in the size of marine turbines.

Fig. 5, page 34, illustrates the progressive increase in the size of turbine-propelled merchant vessels.

Fig. 6, page 35, illustrates the progressive increase in the size of turbine-propelled war vessels.

Table on this page.—Parsons turbines completed and under construction May 31, 1911, in various countries.

List of Principal Papers Referring to the Marine Steam-Turbine.

"The Marine Steam-Turbine and Its Application to Fast Vessels," by the Hon. C. A. Parsons, C.B. Read before the Institution of Engineers and Shipbuilders in Scotland, February 19, 1901.

"The Steam-Turbine and Its Application to the Propulsion of Vessels," by the Hon. C. A. Parsons, C.B. Read before the Institution of Naval Architects, London, June 26, 1903. ENGINEERING, vol. lxxvi., pages 48 and 101.

"The Parsons Marine Steam-Turbine," by the Hon. C. A. Parsons, C.B. Read before the Association Internationale Permanente des Congrès de Navigation, Milan, 1905.

"Progress made in the Application of the Parsons Turbine to Marine Propulsion," by R. J. Walker. Read before the Liverpool Engineering Society, February, 7, 1906. ENGINEERING, vol. lxxxi., page 220.

"The Steam-Turbine on Land and at Sea," by the Hon. C. A. Parsons. Read before the Royal Institution of Great Britain, May 4, 1906.

"Development of the Marine Steam-Turbine," by the Hon. C. A. Parsons and R. J. Walker. Read before the Institute of Marine Engineers, September 29, 1906. ENGINEERING, vol. lxxxii., page 471.

"Marine Steam-Turbine Development," by the Hon. C. A. Parsons and R. J. Walker. Before the North-East Coast Institution of Engineers and Shipbuilders, March 15, 1907.

"Some Practical Points in the Application of the Marine Steam-Turbine," by the Hon. C. A. Parsons and H. Wheatley Ridsdale, Before the Institution of Naval Architects, June 25, 1907. ENGINEERING, vol. lxxxiv., page 61.

"The Combination System of Reciprocating Engines and Steam-Turbines," by the Hon. C. A. Parsons and Mr. R. J. Walker. Before the Institution of Naval Architects, April 9, 1908. ENGINEERING, vol. lxxxv., page 511.

"The Expansive Working of Steam Attainable in Steam-Turbines," by the Hon. C. A. Parsons. Before the Greenock Philosophical Society, January 15, 1909.

"Notes on the Trials and Performances of the S.S. Otaki, Fitted with a Combination of Reciprocating and Turbine Machinery," by Engineer-Commander W. McK. Wisnom, R.N. Before the Institution of Engineers and Shipbuilders in Scotland, August 4, 1909. ENGINEERING, vol. lxxxviii., page 179.

"Propelling Machinery for Warships," by Engineer-Vice-Admiral H. J. Oram, C.B. Before the Junior Institution of Engineers, November 16, 1909. ENGINEERING, vol. lxxxviii., page 703.

"The Application of the Marine Steam-Turbine and Mechanical Gearing to Merchant Ships," by the Hon. C. A. Parsons, C.B. Before the Institution of Naval Architects, March 18, 1910. ENGINEERING, vol. lxxxix., page 379.

"Twelve Months' Experience with Geared Turbines in the Cargo Steamer Vespasian," by the Hon. C. A. Parsons, C.B., and R. J. Walker. Before the Institution of Naval Architects, April 5, 1911. ENGINEERING, vol. xci., page 461.

In the "Evolution of the Parsons Steam-Turbine," by Alex. Richardson, will be found a full review of this subject. (Offices of ENGINEERING.)

FIFTY YEARS' ARCHITECTURAL EXPRESSION OF TACTICAL IDEAS.*

By Admiral Sir CYPRIAN BRIDGE, G.C.B.

NAVAL Architecture is the handmaid of Tactics. Warship design is meant to give expression to the tactical ideas and intentions of the epoch. If we examine the succession of types of men-of-war which have appeared during any particular period, we shall be in a position to discern what the tacticians of the time had in view. Regarding tactics, naval architecture, to use a phrase rather common not long ago, is "History from the Monuments." An investigation of the material remains found on the sites of very ancient cities has enabled scholars to give us a conception of early civilisation and culture, so investigation of the designs of the various ships constructed in the last half-century will furnish us with a clue to the state of tactical knowledge and aspiration during that period. The necessary limits of this paper will allow only our own Navy and its principal ships to be dealt with at all fully. Nevertheless, we shall find the field chosen large enough to contain the illustrations required.

It is just over fifty years since the Institution of Naval Architects was founded; and the date of its foundation nearly coincided with the beginning of a time of extraordinary innovation in naval construction for the purposes of war. In the year 1860 what may be called the seventeenth-century type of man-of-war was still represented in the British Navy. We had two sailing line-of-battle ships in sea-going commission as flag-ships on foreign stations, and several sailing frigates were employed in distant waters. This does not, however, give an exhaustive account of the persistence of the type to which those ships belonged. The steam line-of-battle ships, steam frigates, and steam corvettes—which we were producing in considerable numbers—still had several years of life before them, and resembled in design, appearance, and armament the older classes. The only difference was that, in addition to their sails the later craft had steam propulsion. The gun, as the weapon without a rival, conspicuously dominated tactics.

We have to compare this persistence of a generally uniform type of warship through more than two centuries with the many rapidly succeeding changes that have appeared in the last fifty years. The earlier persistence can in no way be attributed to want of intellectual capacity in the leading naval officers of the day, or to insufficient experience.

When this Institution arose, the tactical aspect of naval architecture was in essentials what it used to be in the days of Blake. Signs of impending change were indeed visible; but they were still too few to disturb seriously the general uniformity of warship design. There is a very remarkable fact to be observed in connection with that long maintained uniformity. This fact makes the contrast between it and the multitude of variations in the last fifty years truly startling. Before the end of the eighteenth century tactical ideas had undergone a great change; but the type of ship remained the same and there was no demand that it should be altered to suit the new tactics. The old method of trying to preserve a rigid line in a fleet action, and of bringing one ship against an individual opponent, had been superseded by the method which we associate with the names of Rodney, of Suffren, and especially of Nelson, viz., that of bringing a number of ships against a smaller number. This led to decisive, and, indeed, to overwhelming victories. It adds to the merit of the great tacticians named that they did their work effectually with the tools which they found in existence. When we consider the course of ship-designing during the half-century just ended, we shall find a very different state of affairs.

This will appear in an enumeration of the several types produced. In the old type, so long adhered to, the object was to mount a battery of many guns. For the line-of-battle the tendency was not to alter the type of

* Paper (slightly abbreviated) read at the Jubilee Meetings of the Institution of Naval Architects, July 5, 1911.

ship or the system of gun mounting, but to increase—within limits—the number of guns. Thus the 44 and the 50-gun ships fell out of the "line," and the 64-gun ship gave way more and more to the 74. In 1860 the object above mentioned was still kept in view. The Warrior, launched in that year, was intended to have a broadside of twenty guns. Her sister ship, the Black Prince, was to have the same. Indeed, except the turret-ship Prince Albert and the Bellerophon, every armoured ship launched between 1859 and 1868 had a broadside—allowing for "pivot" guns—of at least twelve guns.

In June, 1860, Captain Cowper Coles, at the United Service Institution, read a paper entitled "Shot-proof Gun-shields as Adapted to Iron-cased Ships." His proposed ship was really a turret-ship; and it is remarkable that she was to have nine turrets with two guns each, giving, on most bearings, a broadside of 18 guns. This shows that even with him the principle of the numerous battery prevailed.

With the ships that we began to launch in 1871 there came a notable change. From that year down to 1875 we launched fifteen ships, all with turrets and all with a considerably reduced number of guns, though some were of much larger calibre.

In this survey it is to be remembered that the British Navy only is considered at all fully; but the conditions which prevailed in it resembled closely those to be observed in other navies. We ourselves sometimes copied what was being done abroad; and more often we had imitators in foreign fleets. The French, if not the original proposers, were at any rate the first who dared to bring into practical use the armour-clad sea-going man-of-war. The Gloire, launched in 1859, the year before the foundation of the Institution of Naval Architects, may be regarded as the parent of modern armoured ships.

Similarly, the Americans first treated the turret-ship as a practical addition to a fighting fleet; and were enabled by circumstances to be the first to subject the type to the test of actual fighting.

The Austrians were the first of the moderns to make deliberate use of the ram-attack in battle, and by so doing widely extended the introduction of the ram-bow into the naval architecture of the contemporary world.

As regards the Gloire, it has to be said that her type did not indicate a new tactical idea or principle. Like the ships of Blake or of Nelson, she was to have a broadside of as many guns of reasonable power as she could carry when her other weights had been provided for. We have already noticed this feature of the Warrior's design. The number of guns soon began to diminish, and the weight of individual guns to be increased. If we omit the Northumberland, of the same type as the Minotaur, launched in 1863, no ship launched between the year just named and 1887—that is to say, during nearly a quarter of a century—had on a broadside a number of guns which ran into double figures.

Was this due to tactical or to other reasons? Did the ships so armed express a principle of tactics, or was their armament suggested by other considerations? It would seem that in fixing a ship's armament, at the time in question, the governing influence was that of the defensive armour. It was assumed that no gun would be effective if its projectiles could not perforate armour as thick as that carried by the ship herself. This included, or, at any rate, allowed for, a belief that the ship to be fired at would have a side wholly plated with such armour. Acceptance of this view rendered inevitable increase in power of individual guns and decrease in the number of guns on the broadside of any one ship. On this there ensued a vehement and still unended practice-ground contest between gun and armour.

The effects are to be seen in the types of ship produced in different periods. From 1860 to 1870, both years included, we had launched twenty-three armoured ships, of which—not including the converted Royal Sovereign—only three were turret-ships.

From the beginning of 1871 to the early part of 1875 we launched eight armoured ships, all with turrets. There was then a short time during which we launched broadside ships, one, the Téméraire, being of mixed type. In 1879 we reverted to the turret-type, and since that date practically every armoured ship which we have built has had turrets, or, what may be considered a variety of them, barbettes.

The time referred to did furnish some war experience. It included, besides less important conflicts, the American Secession War and the Austro-Italian War in the Adriatic. In the former of these wars armour-clad vessels were first used in belligerent operations on a considerable scale. The war was peculiar in its nature. It was a contest between two belligerents, one of whom had a large navy and the other had scarcely any navy at all. The naval operations consisted principally of engagements between ships and land fortifications. As regards naval tactics on their most important side, viz., the tactics of fleets fighting against fleets, the war furnished no guidance. Nevertheless, the turret-ship made her way into our Navy—at first, as we have seen, but slowly. The small number of vessels of the type which during ten years we added to our Fleet supplies evidence of the inconsiderable tactical importance then attached to the type.

The great change introduced in 1871, the virtual abolition of the broadside system of arming ships, occurred at a time when the contest between the gun and armour was in full progress. Naval attention was concentrated on the problems of making a ship invulnerable with armour, and of finding a gun that would neutralise the desired invulnerability. Tactical considerations receded into the background.

In a naval action in the Adriatic an impressive incident occurred. The Austrians sank an enemy's ship by attacking her with the ram. It was rapidly accepted that this indicated the possibility of devising a new, or reviving an ancient, method of tactics. It was hoped, indeed it seemed to have been believed by some, that this would do away with the superiority in defensive efficiency, which was being claimed for protecting armour. The immediate sequel, however, was that the armour became thicker and the guns individually heavier.

As the defensive armour thickened, so it shrank in surface; and a large proportion of an armour-clad ship was either not defended by armour at all or only by armour of moderate resisting power. The names "iron-clad" or "armour-clad" became obsolete, and were deliberately replaced by the less definite term "armoured." On this, tactics emerged from the obscurity of the previous few years. The French equipped their ships with a secondary armament of guns capable of dealing with the unarmoured or thinly armoured parts of an opponent's ship. Before long we followed suit, putting secondary guns into ships not originally intended to carry them, or deliberately designing ships meant to have a secondary armament.

The weapon—as has been said—dominates tactics; and, as the gun is the principal weapon of fleets, naval tactics have been based on what the gun can do. There are other weapons by no means without importance. Their importance, however, is limited, because they are effective only in special circumstances. The ram has been spoken of already. When conditions are favourable to its use it is a highly effective weapon. The difficulty is to bring about the desired conditions, and this difficulty is so great that the conditions must be rare. In 1871 we adopted as a weapon of war the Whitehead locomotive torpedo. Here, again, it is not the effect of the torpedo, but the possibility of planting it where its full effect will be felt, that is likely to be miscalculated.

It is a remarkable fact that the adoption of the locomotive torpedo and the limitation of a ship's gun-armament to a small number of the heaviest guns that she could carry occurred almost simultaneously. We did not ignore the importance of the torpedo; but we did not make any tactical provision for dealing with its attacks. We made only arrangements for passive defence, by a more minute internal subdivision of a ship's hull, and afterwards by providing obstructions, such as nets.* We did, however, produce special craft which were to use the new weapon, viz., torpedo boats; and we devised a system of tactics for them. This discloses a very interesting state of affairs. A new weapon had come into existence; tactical methods of employing it, involving the construction of a novel class of vessel, had been devised; and yet tactics were silent as to the means of counteracting its employment. Reliance was placed on passive defence arrangements exclusively. We may attribute this to a new conception of the functions of ships of war of the most important class. For more than two hundred years the military value of the warship had been calculated upon what she was capable of doing to an enemy. This was now changed, and her military value was assumed to be based upon what she could endure at the hands of an opponent. She was formally likened to a fortress. A very distinguished authority, writing in 1859, called the ships in our principal fleets "our floating Channel and Mediterranean fortresses." We must believe that this was the consequence of devoting great attention and great talents to the work of trying to render an enemy's attack innocuous by providing a ship with the passive defence of impervious armour. The alternative and older method of frustrating an enemy's attack by bringing against him a superior fire seems at this time to have been given up as hopeless. The probability is that it was regarded—insensibly, perhaps—as hopeless because of the greatly reduced number of shots that could be fired in a given time from the small number of guns that were mounted in a ship. The position, as to defence against the old weapon, the gun, and the new weapon, the torpedo, was that tactics had nothing to say.

The silence of tactics may be ascribed to the then accepted belief that warship design and armament should be based on the intention of destroying an enemy's ship by a single blow. The destructive blow was to be delivered either by the ram at close quarters, or by the torpedo at a moderate distance, or by the heavy gun at longer ranges. No one stopped to inquire into the feasibility of this, or into the relative efficiency of the three weapons. Passive defence, by armour or other material expedient, was deemed both necessary and sufficient.

It is surely worth our while to ascertain why this should have been so. If we examine the then predominant notions in our general policy of defence, we shall find that they favoured the defensive, and largely the passively defensive. It was accepted, perhaps generally, but certainly by the governing authorities, that the British Isles, and especially the great naval ports in them, were likely to be attacked in force by powerful enemy. The old plan, which, under such leaders as Hawke, St. Vincent, and Nelson, had proved so effective—viz., the preventing of the enemy from getting near enough to deliver his attack—seems to have been forgotten. It was taken for granted that we could not stop our enemy from coming to any point at which he wished to arrive; and that all that we could do was to get behind our fortifications and under their shelter fight him as well as we could. That this would mean abandoning the sea to an opponent, with all the prodigious consequences of such procedure seems not to have been understood.

The waters in which our fleets were wont to anchor were studded with armour-clad forts. It was to these works of defence that the eminent authority above quoted had likened our more important ships. Standing on the defensive was, as it were, in the air; and the prevailing sentiment governed the conception of what a man-of-war ought to be. If she could be made so, she was to be impenetrable by an enemy's projectiles. Somebody heard, or dreamt that he had heard, the Navy crying to the naval architect: "For God's sake keep out the shells!" Armour was again thickened, and, being thickened, was again reduced in area; so that shells were effectually kept out of a part, a gradually diminishing part, of the ship, whilst free ingress to the rest of her above water was conceded to them. It was not seen that there was a reasonably effectual method of keeping an enemy's shells from entering any part of the ship, armoured or unarmoured, viz., by overwhelming him with the fire of your own guns. Admiral Farragut had said: "The best armour is the return fire." Like most apophthegms, this looks at first sight exaggerated. The truth that it contains was not recognised. So, in individual ships, armour was given greater power of resistance, whilst guns decreased in number. The power of a gun was, indeed, increased; but with the object of enabling it to send its projectiles through the more resisting armour on an opponent's hull. The Devastation, Thunderer, and Dreadnought, launched between 1870 and 1875, gave expression to the dominant ideas of the day, when tactical principles attracted so little attention that the word "tactics" was rarely heard, and when it was heard it was applied to the practice evolutions or drill of a fleet.

If tactics ceased to attract attention, naval architecture by no means stood still. Naval architects were every day showing that they could meet every reasonable demand. If the results of their efforts had no great tactical importance, that was certainly no fault of theirs. A particularly brilliant period in the history of naval architecture coincided with a period of marked dulness in naval tactics. To what are we to ascribe this paradoxical condition? We are justified in ascribing it to the absence of fixed principles from the minds of those whose proper sphere was tactics. Perhaps, without foreseeing the effects of their procedure, they gave up being tacticians in order to deal with details of naval architecture. It is not easy to find any other explanation of the variety of types of ship produced during the period under notice. The variety by itself was sufficient to prove that there was no fixity of tactical principle. It also disclosed symptoms of a belief that architectural design should regulate tactics and not tactics regulate design. Historical monumental proof of this exists in the ships constructed at the time.

The French, who have shown greater aptitude than any other people for treating naval affairs scientifically, were the first to break away from the position above indicated. They understood that a battle between fleets would not be a mere matter of perforating or failing to perforate a restricted area of thick armour. They had a vivid perception of the great tactical principle that concentration of the effect of weapons should be the end aimed at, and that concentration of the weapons themselves is merely the means. Therefore they armed their ships in accordance with the principle. Other nations had to follow their example. The ships launched or designed for our own Navy during the last dozen years of the nineteenth century and the first two or three years of the twentieth supply monumental evidence of the reviving but far from dominant influence of tactics.

To follow the course of naval architecture within the last half-dozen years would be likely to lead us into contentious questions, which, in a paper like the present, it is best to avoid. Attention, nevertheless, may be properly invited to some aspects of it which appear to reproduce the conditions of the time when the turret-ship excluded other types of ship from the fleet. The object then was to obtain great concentration of defensive and offensive material in individual ships, and that object has reappeared of late. Another object was to make the concentration more powerful than any other country had made it. Here, again, we can observe similarity to the aims of the earlier period. The accompanying circumstances now are like those that showed themselves then. There is now, as there used to be before, an oscillation in superiority of material power as exhibited in the augmented displacements and weights of guns. To-day one country has the bigger ships and heavier guns; to-morrow this kind of superiority has gone to some other country, which, in its turn, will be surpassed in these things. The important question that we have to face is this: Is the oscillation due to recognition of tactical principles, or is it a contest in architectural development? That question, we may be sure, will be answered, if not by this generation, then by a future one, and the ships which the great navies of the world are adding, and have lately added, to their lists will remain, whether or not as efficient components of a fighting fleet, at any rate, as monuments to show the world the extent to which, at this present day, the principles of naval tactics found adequate expression in architectural design.

* There is not room in this paper to deal with the class of craft called "destroyers," which, though they have been converted into merely larger torpedo boats, were originally introduced with the deliberate object of acting against torpedo boats. Their adoption was based on a real tactical principle, which, owing to the plan of using them as torpedo boats, had been lost sight of.

THE TASMANIAN GOVERNMENT RAILWAYS.—Mr. G. Wishart Smith, general manager of the Midland Railway of Western Australia, has been appointed sole commissioner of the State Government Railways of Tasmania.

THE INSTITUTION OF CIVIL ENGINEERS.

CONFERENCE ON EDUCATION AND TRAINING OF ENGINEERS, 1911.

(*Concluded from page 868 of our last volume.*)

SECTION II.—SCIENTIFIC TRAINING.

*The Value of a University Degree in Engineering Science in Relation to Professional Competence.**

By Professor STEPHEN MITCHEL DIXON, M.A., B.A.I., M. Inst. C.E.

THE competent engineer is one who can deal effectively with materials and men. While it cannot be claimed that three or four years' good work at an engineering school gives this competence, still it can be shown that for the ordinary man it is the best method of obtaining the necessary preliminary training, and so the university degree becomes the first step of a long ladder leading to eminence in the profession.

The training of the engineer may be divided into theoretical and practical, but this is merely for convenience in discussion, because the two divisions can never be separated entirely. Speaking broadly, however, the theoretical part or basis of the engineer's education is that which is more or less complete, as far as most men are concerned, when they receive the degree in engineering. The practical part of his education, beginning at college, should continue as long as the engineer remains in practice.

The unique position held by the Institution of Civil Engineers in this country would have seemed favourable to the early systematising of engineering education, but fortunately this has not happened. By wise encouragement, the individual efforts of those seriously interested in engineering education have arrived at solutions of the problems involved, and the experience gained by others should enable us to choose methods giving the best results. Moreover, the evils due to a too early standardisation, which would have given a cramped and narrow system, have been avoided, If we examine the courses which at present lead to degrees in engineering science, we see the results of this policy. It will be seen that a broad and sound training in the underlying principles, education in its true sense, and not the mere imparting of information, have been the objects sought.

While it has been said that both sides of the engineer's training begin at college, there is no doubt that the work carried out for the degree must deal mainly with principles, and should be as broad as possible. Details of current practice will be noticed only as illustrations of principles. In dealing with materials, the engineer needs a knowledge of mathematics, physics, and chemistry; and if he is to avoid mistakes, his knowledge must be very exact, and at his fingers' ends. The courses in mathematics, physics, and chemistry naturally lead to those in surveying, stresses in structures, and properties of materials. All these are technical subjects, it is true, but they can be far better and more easily taught in the class-room, field, laboratory, and drawing-office of a university than in the engineer's office. When the student has a sound knowledge of the principles involved in the study of these subjects, he will make rapid progress in the details of practice.

Instruction in the above subjects, important as it is, should form only part of the general education of the young engineer, if he is to be fitted to hold more than a subordinate position in the engineering profession, for, as stated earlier, the engineer must deal with men as well as materials.

A liberal education is essential: literature, history, philosophy, all subjects which tend to broaden a man's outlook should be studied, and this is even more necessary in the case of engineering students than in the case of those who intend to follow other professions. Of course, unless a university education leads to further reading and research, one of the most desired objects is not obtained; but, owing to the nature of his employment, the engineer frequently has for several years few opportunities for reading outside his work, and so should make up for this by the keenness of his interest in these so-called "outside subjects" while at college. We take it for granted that the successful man in any other of the professions will be one who has already made his mark at the university, and it is certain that the success in a great measure is due to the trained ability which enables the possessor to influence his fellow-men. The general culture which comes from college life as well as from college study is an asset in the engineering profession not to be despised and not easily obtained. The man who leads his fellow-students in the class-room, in sports, or in the debating society, is equipped in a very real way for success in his profession.

The work done at engineering schools is serious and painstaking. Much has been written lately about examinations and degrees in engineering, but those familiar with the work of engineering colleges can testify that the profession has no reason to fear that the status of the civil engineer will not be upheld by the graduates in engineering. The final examination is but a very small part of the requirements for a degree. Three or four years of solid work under personal teaching sifts out a large proportion of those entering on the courses, while at the same time few students who possess industry and average ability should fail to satisfy the present requirements in the specified time.

No system of education is above criticism. If we take an interest in the objects of the system, we should see that our criticism is fair and helpful. At present the university method is recognised as the only generally applicable method in every country but our own. The objections to the system in this country may be found stated by two classes of engineers: Those who have in their early days entered university courses and then dropped them before grasping the meaning of the instruction offered, and those who have risen to eminence in their profession before university training in this country became general. The former are answered by the fable of Æsop of the fox who tried to make the best of a serious accident; the latter are reminded that competition in the profession is becoming keener every day. English engineers now find in every country friendly rivals who have spent a large part of their time at engineering colleges, and it would be unjust to the rising generation if they were not able to start with advantages equal to those of their competitors. It is not long since that it was not unusual to find, in some of the larger engineering schools in America, English students attracted by the superior equipment and facilities for research. At present our students are more fortunate. At home they can, at well-equipped colleges, receive instruction which is admitted to be efficient and up to-date. In fact, the stream of students from newly-developing countries without engineering schools of their own is being in part diverted from the United States to this country.

In arranging this discussion on engineering education for members of the profession who have already attained eminence in its practice, the Council of the Institution had evidently in view the one difficulty which exists for the moment in England. While in other professions a university degree is regarded as the first requisite, and so leads directly to employment, there is still a feeling in some quarters that the university graduate is rather in the way in an engineer's office. Matters, however, in this way are improving. Once engineering firms recognise the advantage of having assistants thoroughly trained in the principles underlying practice, and whose training also fits them specially for adopting new ideas rapidly, they will be only too glad to co-operate with the universities in completing the education of the engineer. A method already adopted on some railways in the United States and in Australia has been in work for some time on at least one railway at home. In this case we have the principle of co-operation firmly established, by which the college graduate obtains his practical experience in the best way possible. Entering the service of the company under a small but gradually increasing salary, the graduate in engineering is under agreement to stay a specified time. During this period the engineering staff of the company consider that there is an obligation on their part to see that the duties of the junior assistant are so arranged as to give him a wide experience. One railway company in the United States reports that the services of men so trained by them are so eagerly sought by other companies that they cannot satisfy the demand. This principle of co-operation might be extended largely, and the greatest gainers in the end will be the employers, while at the same time the status of the junior engineer will be greatly improved; and not only this, but by the interest thus taken in engineering colleges by engineers in practice, modifications in the courses may be suggested, and students will be encouraged by the knowledge that the training, the successful conclusion of which is indicated by a degree, is recognised by the leaders of the profession as the right and necessary preliminary to practice.

* Read at meeting of Section II., held Thursday, June 29, 1911.

*The Value of a University Degree in Engineering Science in Relation to Professional Competence.**

By Professor CHARLES FREWEN JENKIN, M.A., M. Inst. C.E.

IN order to estimate the value of a degree in engineering science, it is necessary to understand clearly what the possession of the degree means. It means that the graduate has spent some years in passing through a carefully-arranged course of study in those fundamental subjects which should form the basis of engineering education, and also that he has attained a certain standard of proficiency in them as far as that can be tested by examinations.

It is no longer necessary to urge the importance of theoretical training. Engineering education should consist of three parts—a basis of general scientific study; a middle structure of applied science—that is, of science specialised, extended and adapted with a view to its bearing on professional practice; and, lastly, that kind of knowledge of practice which can be gained only by coming directly in contact with it.

This is now recognised by the Institution of Civil Engineers, which requires proof that applicants for admission shall have had both theoretical and practical training. The latter can only be obtained by an apprenticeship or its equivalent, and I sincerely hope that the Institution will always maintain its requirements in this respect, and not accept a knowledge of college workshops as equivalent to a knowledge of real practice, which it can never be. I am aware that much that is useful can be taught in college workshops, but I believe that it is better for the student to learn these things in the real shops, where he will at the same time acquire a fund of practical experience which he cannot in college. As Sir William Siemens said, "College teaching should deal very much with principles and very little with details."

The first part of the training—the theoretical part—with which we are specially concerned, can be obtained more or less efficiently in various ways. It is this part which the entrance examination is intended to test, but a degree is a very much better proof of the possession of a good theoretical training than any examination can be. This is the first reason I would bring forward for regarding a degree as of value.

That an examination is in general a poor expedient for ascertaining a student's proficiency is becoming more widely recognised every day; it is, however, less unsatisfactory when held on the completion of a definite course of study than when it is used to test general scientific knowledge. Further, the degree course contains much that cannot be included in the examination at all; for example, much of the student's time is spent in the laboratory learning how to measure accurately all sorts of physical quantities, and to carry out tests on all sorts of machines—steam, electric, hydraulic, &c. Laboratory training can only be obtained in a college; its value is very great. To quote my father's words, "There is no teaching more practical, more immediately fertile in results, than that which can be given by the man of science in his laboratory." Again, there is the teaching in the drawing-office, where the student learns to use his theory in the preparation of actual designs, and the field course of surveying, during which he learns to handle his instruments skilfully and accurately. These are all implied in the degree; but it is almost impossible to take any account of them in an examination. To quote Dr. Ewing's reference to the Institution examinations in his admirable paper on engineering education, read at the recent Imperial conference:—"To pass an examination in certain sciences is one thing; to have had the advantage of a university or college course in which the same sciences are well taught is quite another thing."

The value of a degree may be considered from another point of view. What training is best for the boy when he leaves school—best in a wide sense? Is it better for him to go to college or not? for this is what the degree implies. To spend some years at a university is an education in itself and will be a permanent asset in the boy's life. The value of this part of education was well stated by W. B. Rogers, the founder of the famous Massachusetts Institution of Technology in Boston:—"We believe," he says, "that the most truly practical education, even in an industrial point of view, is one founded on the thorough knowledge of scientific principles, and which unites with habits of close observation and exact reasoning a large general cultivation."

This general cultivation is the feature of all university life—specially perhaps in the older universities. It is a matter on which we may congratulate ourselves that the two oldest universities now open their gates to engineering students.

The value of a degree may be considered from a third point of view. Sir James Inglis, in his presidential address in 1908, said: ". . . it ought to be laid down as a principle that all public money derived from rates and taxes should be, so far as it is applied to engineering construction, expended under the direction or control of definitely qualified engineers, as is already the case in many countries."

If the engineering profession is to be brought under State control, as medicine is, and also the law—in a modified sense—it would appear to be wise to make the basis of qualification as broad as possible by recognising the engineering degrees of the universities as a necessary qualification, rather than a certificate by a single institution, even though that institution were our own.

An engineering degree then may be looked at in three lights: As a guarantee that the holder has had the best theoretical training and has profited to some extent thereby; as the final step in that type of liberal education at the universities of which England is justly proud; as a broad basis on which State recognition of our profession may be founded.

The regulations drawn up by the Institution for the admission of students and members are wisely framed at present so as to recognise many different types of training; but if the reasons I have advanced in favour of the engineering degree are valid, it would be well for us to look forward to a time, not too far distant, when the possession of a degree shall be a necessity in engineering as it is in medicine.

*The Position and Uses of Engineering Laboratories in Relation to Education at College.**

By Professor WILLIAM ERNEST DALBY, M.A., B.Sc., M. Inst. C.E.

THE outstanding feature of our modern system of scientific education is the laboratory. It is now recognised as an essential instrument in all branches of scientific education. The reason is not far to seek. In a lecture-room a student hears things, but in a laboratory he does things; and a normal student remembers what he does, and forgets the greater part of what he hears. A youth anxious to become an engineer is generally born with a desire to do things; and thus the material which we have to train in our engineering colleges is peculiarly susceptible to laboratory teaching. Through the work he does in the laboratory comes the desire to hear rightly in the lecture-room.

An engineering laboratory may be designed from the two distinct points of view of teaching and research. The two ideas are complementary to one another rather than antagonistic, and both must be kept in view in the general design of the laboratory of a great school.

From the point of view of teaching, the individual items of the apparatus provided should be numerous, typical, and small, so that there may be plenty of experiments for small groups of students to carry out for themselves. For example, five 20-horse-power steam-engines, each properly equipped with measuring apparatus, are better than one 100-horse-power engine. Later in the course a student may form one of a large group testing a large steam-engine, but his early work on the smaller

* Read at meeting of Section II., held Thursday, June 29, 1911.

plant will enable him to perform his part with a comprehensive knowledge of what is being done by the other members of the group. He will thus do the work more intelligently.

In an engineering laboratory the students must do the job, and not watch the job done by the professor on a large and expensive piece of apparatus too costly to be entrusted to them.

From the point of view of research, the chief provision to be made is space, time, and a workshop in which research apparatus can be made, together with apparatus sometimes of an expensive kind, but often inexpensive. Any of the apparatus provided for the instructional course may, from time to time, be made the subject of a research; but in such an event it must be withdrawn temporarily from the routine work of the laboratory.

The equipment of an engineering laboratory cannot be specified without a clear idea of what it is that we aim to teach.

Amongst the many things that may be put down, three, I think, stand out clearly—namely:—

1. The fundamental principles on which engineering science is based.

2. The physical properties of the materials of construction.

3. The methods of measuring that elusive thing, energy, in the many guises it assumes.

The fundamental principles upon which engineering practice is based are few in number, but their applications are almost infinite. A principle can only be thoroughly grasped through a study of its applications. Hence a principle should be taught by means of applications selected from those which have a bearing upon engineering. For example, both the astronomer and the engineer must thoroughly apprehend the principles embodied in Newton's laws of motion. The budding astronomer might fitly be taught by applications of these laws to the solar system. An engineer would learn them by their applications to the motion of machinery, the flow of water, and, may I say, the balancing of engines. But the inversion of the selection would be disastrous both for the astronomer and the engineer, although the aim is to teach both of them exactly the same principle. The engineering teacher has a vast and interesting field of applications from which to make his selection, and the suitability of his choice will depend largely upon the extent of his scientific knowledge and practical experience.

All students of engineering should gain some familiarity with the physical properties of steam and gases and with the materials of construction. There should be a complete equipment of small testing-machines in order to provide for numerous individual experiments simultaneously, together with some large machines for research work.

The fundamental principles of thermo-dynamics should be taught through their applications to estimate the efficiency of heat motors of all kinds. There should be a full equipment of heat motors small enough to be entrusted to a group of two or three students, together with a few large engines and typical steam-plant for the more extended study of the subject.

A student learns a great deal by testing heat-engines. He learns how to measure the flow of energy when it is associated with such diverse agents as gas, steam, water, and ether, and in the form of mechanical energy. In the making of the heat balance-sheet he unconsciously, perhaps, uses the principle of the conservation of energy whilst he is consciously hearing lectures of how this principle underlies the science of thermo-dynamics, and how this science enables him to estimate with justness the performance of the engine he actually tested in comparison with the ideal engine of thermo-dynamics.

Time prevents me from enlarging on the educational value of the work in the electrical laboratory. The elusive nature of the agent with which electrical energy is associated makes the work both fascinating and absorbing.

Above all, in passing through the course, the student should catch something of the spirit of research which should brood over every engineering laboratory, from the smallest to the greatest. If he is successful in this, he will go forth trained to think for himself and to act for himself, and with a desire to add his contribution to the vast accumulation of scientific and practical knowledge which is our heritage from the great thinkers and engineers of the past—men whose names are famous not only on the roll of the Institution of Civil Engineers, but on the larger roll of the British Empire.

---

*The Position and Uses of Engineering Laboratories in Relation to Education at College.**

By Professor JOHN GOODMAN, M. Inst. C.E.

THE value of engineering laboratories for educational purposes, and for obtaining experimental data of an engineering character, is now so extensively recognised, that it is quite unnecessary to spend time in discussing the general question; but since the equipment, the nature of the work done, and the methods of carrying on the work vary so widely in the laboratories of different colleges, it appears to be desirable to discuss these questions with a view to increase their usefulness and efficiency.

Object of Laboratory Training.—It is well at the outset to recognise that the equipment and scope of an engineering laboratory differ essentially from that of a college workshop. The work carried on in the latter is mainly for the purpose of teaching the art or trade of engineering (as to whether such workshops should be attached to colleges or not is a much debated point, upon which very definite opinions on both sides are held), but the work done in the former has the sole object of teaching the principles which underlie that art or trade. It is possible, in certain cases, that laboratory work may overlap that proper to the workshop, but in general the functions of the two are distinct, and must not be confused.

However able a teacher may be, it must often happen that students do not get a thorough working knowledge of a subject from attending a course of lectures, although they may have no difficulty in following the treatment during its delivery; if, however, properly-schemed laboratory work can be arranged to run concurrently with the lectures the student is brought more closely into touch with the concrete side of his subject, and thereby not infrequently discovers his own shortcomings. It is, of course, well that he should be brought face to face with difficulties, and, instead of being spoon-fed, he should, in the early stages, be left severely alone to worry out his problems; but if actually beaten, then, and not until then, should the director of the laboratory come to his assistance. Such a course will often arouse interest where lectures fail, and will reveal to him discrepancies between theory and experiment; inquiry into the reason for such discrepancies are of real educational value; and if the student possesses "grit," it will be a great incentive to him to dive more deeply into the matter. Later in life, when such difficulties arise on a larger scale, his familiarity with scientific methods of dealing with obscure problems will enable him to attack them with a directness and certainty that are lacking in the untrained man.

Amongst other important phases of laboratory work the following appear to be worthy of special note:—

The engineering laboratory affords the student an excellent training in the carrying out of experiments for the purpose of obtaining accurate data, and he cannot fail to be early impressed with the paramount importance of keeping all the conditions of the test constant except the two variables under consideration. He, moreover, discovers that absolute accuracy in data is rarely, if ever, attainable, and therefore the use of many significant figures is not only absurd, but tends to deception. In the author's laboratory the first work done by students consists in the measurement of certain quantities by three or four different methods, with the object of impressing upon them the fact that the methods themselves are not perfectly accurate, and, even if they were so, the personal equations of the workers would affect the result obtained. It is believed that it is important for students to realise early that extreme care in the choice of methods and in the use of apparatus is essential if any high degree of accuracy is required.

In certain cases the laboratory work is valuable in showing how far theory and experiment agree, but great care is necessary in order to prevent students jumping to the conclusion that there is actual disagreement because their own imperfect, inaccurate experiments do not give the results that the theoretical treatment would lead them to expect. It is, however, believed that it is a mistake in the first instance to insist on students worrying about minute accuracy. Until their ideas get somewhat broadened, such attempts at accuracy absorb a large amount of time quite out of proportion to the importance of the result obtained, but later on a certain amount of experimental work requiring a high degree of accuracy is a most excellent training.

Equipment.—Before purchasing apparatus for the equipment of an engineering laboratory, it is of great importance that a general scheme should be drawn up, setting forth definitely and clearly the lines on which the proposed work is to proceed; in the author's opinion the aim should be to make all apparatus as simple as possible, and each piece should be designed to bring out clearly one particular point, all unnecessary complication being dispensed with. Teachers are very liable to forget that the average student is unable to appreciate the refinements and intricacies of highly complex and elaborate apparatus, which, as a rule, completely mystifies him. Distinction must always be drawn between apparatus which may be used by the staff for their own education and for research work and that required exclusively for students. In this connection it is suggested that it is better to make use of commercial tackle, such, for example, as ordinary pulley-blocks, screw-jacks, &c., rather than the amateurish polished brass and painted wooden models so often offered for sale for use in colleges.

The experimental steam-engines found in college laboratories are frequently fitted with a maze of intricate appliances for the purpose of enabling the engine to be worked under a great variety of conditions, with the result that students are very liable to get erroneous ideas as to the essentials of any given type of engine. Such engines are necessarily not stock articles, hence they have to be specially constructed for the purpose, and are, therefore, very costly. The author suggests that it would be better in every respect to purchase two or three commercial engines of different types for testing purposes rather than crowd so much complication on to one experimental engine. Unfortunately, all apparatus soon gets out of date, and unless a college is very wealthy it cannot afford to clear out the old-fashioned machinery every few years and replace it with new. In some cases enterprising firms lend engines and plant to colleges for testing purposes on condition that the results of all tests shall be supplied to the makers in return for the loan, and when the firm in question brings out an improvement the obsolete plant is exchanged for the new. The arrangement from the college point of views is, of course, ideal, and the firms in question are not entirely losers by the bargain.

In all tests where a great variety of conditions may prevail, it is impossible, on account of time, for one group of students to work under each set of conditions, therefore it appears to be desirable that a definite scheme of testing should be drawn up, which may possibly take years to complete; then as each result is obtained, it should be plotted on a squared paper chart exhibited in the laboratory, thus enabling each group of students to benefit by the results previously obtained. If isolated tests are made under random conditions they are robbed of much of their educational value, and the results obtained are of little or no permanent value.

The extent to which stereotyping should be allowed in the work of an engineering laboratory is one well worthy of the most earnest discussion; all will be agreed that it is an utterly bad system to have the apparatus required for each experiment set out permanently in working order, and to give printed detailed instructions and log-sheets to each student, which he mechanically follows. The following of such a system entirely crushes all originality, and makes the student into a mere machine. In the early stages of the laboratory course some approach to this system may be tolerated perhaps, that is, during the period in which the student is learning to take and book observations; but after he has once got over the initial stages he ought to rig up his own apparatus, check it for accuracy, make out his own log-sheets, and reduce his results. Of course he requires more supervision when working under such conditions, but he certainly gains experience of a far more valuable character than under a stereotyped system. The extent to which he can go in this direction largely depends upon whether he has been in commercial engineering workshops before taking up his college course. In tests of a more important character it often happens that the student lacks the necessary manipulative skill required for carrying out the experiments if he has not had a previous practical training in works.

Laboratory Routine.—The staff of an engineering laboratory usually consists of a director with one or more assistants and skilled mechanics. It is of vital importance that the director should be a man familiar with practical work, or he may unwittingly encourage students to play with unreal problems, which tend to divert their attention from the actual difficulties that arise in the life of an engineer. The author on one occasion visited a technical school in which the students were observed to be busily engaged in testing the buckling strength of wooden matches, from which strut data was to be evolved.

A considerable amount of skill and much tact is required of the director who gets his laboratory to run smoothly and efficiently. The following regulations are found greatly to assist in smooth running:—

All observations to be recorded in note-books or on authorised log-sheets, and not on odd scraps of paper.

The results, after reduction, to be entered neatly, with necessary curves, sketches, descriptions, and explanations, in a laboratory note-book, having alternate pages of squared paper.

The most important results to be entered in a record-book kept permanently in the laboratory.

The students' note-books to be inspected by the director or assistant in charge after the entry of each experiment, and no fresh experiment to be started upon before the previous one is completed and entered up.

A large sheet posted up in the laboratory, having a vertical column for each experiment and a horizontal line for each student, to be starred with an india-rubber stamp as each experiment is completed. By this means the work already done by each student can be seen at a glance.

Much inconvenience is sometimes caused by students not returning measuring-instruments and other apparatus to the proper place after the completion of the experiment. Therefore each student in the Leeds University is provided with brass checks, similar to those used in works, and when he requires to use thermometers, indicators, &c., he goes to the stores and deposits his check with the storekeeper for each piece of apparatus. The check is hung on a peg close to where the apparatus is kept. If he fails to return the apparatus at the proper time and in good order, he is charged for it by a reduction from his laboratory deposit.

In order to keep a record of the time spent in the laboratory, special sheets are put up every day, which are initialled by the student to certify his attendance before he leaves.

---

*The Position and Uses of Engineering Laboratories in Relation to Education at Colleges.**

By Professor BERTRAM HOPKINSON, M.A., B.Sc., F.R.S., M. Inst. C.E.

THE classification and analysis of the phenomena presented to the engineer in the practice of his art conveniently called "Engineering Science," occupies a position intermediate between biology, which is mainly based on the observation of Nature, and physics, which is chiefly experimental. It is founded on the laws of motion, of heat, and of electricity, whose action is investigated in the physical laboratory; but it is concerned with the working of these laws under conditions comparable in their complexity with those under which the same laws work in living things. This is obviously true of the greater natural forces, such as the winds and tides, whose action it is the engineer's business, so far as possible, to control. It is impossible to bring these things into the laboratory, and to subject them to experimental analysis, though experiment may be of great help in interpreting observation of them. In other branches of engineering science—for example, in the study of the production and use of power—there is not the same physical limitation on experiment, but there is a commercial limitation which is

* Read at meeting of Section II., held Thursday, June 29, 1911.

* Read at meeting of Section II., held Thursday, June 29, 1911.

just as effectual. Complete experiments on a full scale under commercial conditions cannot be made because no one will pay for them, or allow his business to be disturbed while they are being made. Moreover, the commercial element and the human element are the most important among the conditions under which engineering phenomena go on and which determine their course. In a laboratory experiment they are as little reproducible as is the texture of a full-sized wind. Thus engineering science must be based on the intelligent observation of things as they occur in practice. As in biology, experiments in an engineering laboratory may be of great assistance, but in interpreting their results it must never be forgotten that the artificial control of conditions, which is of the essence of experiment, is of itself a disturbing factor, analogous to that general effect on the subject of a vivisector's operation, which always lessens, and may destroy, the value of his conclusions when applied to the normal animal. On the other hand, it cannot be doubted that the necessary difference between natural conditions and the artificial atmosphere of the laboratory is less far-reaching and its effects are more readily foreseen in engineering than in biology. Experiment plays a part which, though still subsidiary, is relatively more important. Especially is this the case in the applications of electricity.

The position of the engineering laboratory as an instrument of education is not quite the same thing as its position in relation to research, but is closely related to it. In a discussion, some twenty years ago, on the proposal to establish an Engineering School in Cambridge, it was pointed out, by way of justifying the innovation to that ancient university, that it was as good an education thoroughly to test a steam-engine as to determine the velocity of light. It might well have been said that it was better, for in the engine trial the student is introduced to phenomena under conditions which, in their complexity, resemble those of real life, and which can only partially be controlled. He can vary steam-pressure, load, and perhaps speed, but he cannot, within the limits of an ordinary trial, control such important factors as the dryness of the steam-supply, or the temperature of the cylinder walls. Thus he learns in a simple way to use his judgment in interpreting data, and to recognise how in a complex mechanism it is impossible to vary a single element without at the same time affecting a number of others. This training of the faculties of criticism and observation is valuable to anyone, whatever profession he is going to follow, and it cannot be obtained in the same degree from the experiments ordinarily performed by students of similar standing in a physical laboratory. To the engineering student there is the additional advantage that he sees the application of scientific principles to things of the same sort as he will meet with in after-life.

These considerations, together with a frank recognition of the fact that by no possibility can the conditions of practical work be completely reproduced in the laboratory, lead to a fairly definite conception of its position and uses. In the first place, industrial apparatus, even of a simple character, is too complicated to be used as a means for demonstrating elementary physical laws to students who are quite ignorant of their working. Hence work in the engineering laboratory proper should be preceded by a short course of ordinary physical experiment under the simplest possible conditions. Provision is made for this in nearly all college courses, and it is unnecessary to discuss it in detail. Assuming that he has thus acquired a knowledge of the fundamental scientific principles, the student's work in the engineering laboratory will be directed largely to tracing their operation under more complex circumstances. For this purpose small units of plant of a simple character are quite adequate. Everything that such a student can learn in an engineering laboratory in the time at his disposal he can get from a 10-horse-power engine, from a 5-ton testing-machine, and from plant on a similar scale in the other branches of his study. A triple-expansion engine teaches him no more than a compound; a four-cylinder petrol-motor little, if anything, more than a single-cylinder gas-engine. In fact, the smaller and simpler machines are better for his purpose, because they are more easily handled, and he can be left more to himself. The author remembers seeing in a technical school an engine of several hundred horse-power, which was being tested by some fifteen or twenty students. They were taking readings according to a set scheme, one reading a thermometer, another a pressure-gauge, and so on, and all the readings were being entered on a beautiful printed sheet. On the same day he happened to speak to a schoolmaster, who described how he was in the habit of setting his boys two or three at a time to indicate the laundry-engine at his school, and test its steam consumption with an improvised condenser. There cannot be much doubt that the schoolboys learnt more than the students, and that the money paid for that large engine would have been better spent on twenty small engines.

But, though small, the machines in the engineering laboratory should be real commercial machines, such as are bought and sold in the ordinary course of business, and the students should use them under ordinary working conditions. This is, of course, quite consistent with the use of the most elaborate measuring arrangements that the ingenuity of the professor or demonstrators can devise, provided that they are such as a commercial user of the machine would tolerate. For instance, a gas-engine may have thermometers stuck all over it, it may suck its air through a hole for the purpose of measurement, and it may discharge its exhaust into a calorimeter, but it is not to be run at less than its normal speed in order to get better indicator diagrams, nor is the valve-setting to be altered for the purpose of improving the measurement of the air. Extreme variation of conditions is necessary for the purpose of research; but the ordinary student is not doing research, nor is it his object to learn in detail about the working of a special machine. His use for the engineering laboratory is to learn generally how to extract from an experiment conducted under severe limitations all the information that it is capable of affording. In doing so he will consolidate the knowledge of natural laws, which he is supposed to have acquired previously in an ordinary physical laboratory, and will learn their limitations; he will also pick up many facts about the working of machines which may or may not be of direct use to him, according as he meets with these particular types in after-life or not. But these are by-products, and in the author's view the engineering laboratory should be designed and organised with a single eye to the primary educational use which has been indicated.

SECTION III.—PRACTICAL TRAINING.

*The Relation of Engineering Employers and Colleges from the Point of View of the Practical Training of College Students.**

By Professor JOSEPH ERNEST PETAVEL, D.Sc., F.R.S., Assoc. M. Inst. C.E.

A GOOD general education, a wide scientific knowledge, and a sound practical training constitute qualifications essential for success in the engineering profession. The engineering employer and the university teacher are therefore co-partners, jointly responsible for the success of the educational work; and it follows that some close co-operation is eminently desirable.

Any discussion of the relationship between employers and teachers must be primarily based on some definite understanding with regard to the aim of university teaching and the qualifications attainable by the average college student. On both these questions a considerable divergence of opinion exists, and it is merely with the object of providing, as briefly as possible, a basis for systematic discussion that the following apparently somewhat dogmatic statements have been drafted.

1. A boy intending to qualify as a civil or mechanical engineer would pass the university matriculation examination at the end of his school career, and afterwards spend a year in a mechanical workshop before entering the university.

2. The university teaching should be scientific in its nature and wide in scope. A reasoned discussion of present practice and future possibilities should take precedence over merely descriptive treatment. The student should be taught to understand fundamental principles and make an intelligent use of mathematical analysis, not to memorise unimportant details and empirical formulæ. Finally, early specialisation should be discouraged. The educational work of the university is brought to a successful termination when the student has been taught how to learn.

3. The object of the engineering laboratory is to afford illustrations of the principles referred to in the lectures, to familiarise the student with the methods of testing materials or machines, and to prepare him for the practical training which it cannot replace.

4. The university degree implies a certain standard of work, knowledge, and intelligence, but the ultimate success of the graduate as an engineer will depend primarily on his personal characteristics, and secondarily on the opportunities offered him during and after his practical training.

The engineering employer cannot anticipate that a university graduate will be of much assistance during the first few months, but should require him to reach a satisfactory standard of efficiency before the end of the first year, and expect him to deserve some reasonable remuneration during his second year.†

5. The head of an engineering department is always glad to select and recommend a man suitable for any position which is offered.

6. The engineering employer can co-operate in the educational work of the university by a frank and friendly criticism of the methods adopted. By offering to take college graduates on a six months' trial he can form a personal judgment of the qualifications of the men and select those best suited for the work he requires.

The Relation of Engineering Employers and Colleges from the Point of View of the Practical Training of College Students.‡

By JAMES WILLIAM HORNE, B.Sc., Assoc. Inst. C.E.

THE requirements of the Institution's bye-laws relating to election are: A sound general education developed on lines suited to subsequent scientific study; a complete knowledge of those branches of science which form the basis of engineering; and practical training under actual engineering conditions, adapted—to quote from the last report of the Council—to fit persons to take part in the design, as well as in the control and direction of engineering works.

The Committee on Engineering Education and Training, in their report of 1906, made it very clear that youths training as engineers should, if possible, spend at least two years of that training in systematic scientific study at a fully-equipped engineering college, in order to make themselves more efficient for their future professional career, and in part to fulfil the requirements for election into the Institution. The committee at that time could only generalise as to the most suitable period when the young engineer should proceed to college for this scientific education. This admirable and exhaustive report has exerted a very effective influence in improving the system of engineering education and training, and, as a result, the engineering training of the university and college type of to-day is a great improvement on apprenticeship practice existing some years ago. The university and college type of trained engineer is of recent creation, and in every field of engineering his influence is being felt. This type has undoubtedly come to stay, and will be produced by these institutions in ever-increasing numbers.

The consensus of opinion among engineers of experience and standing of the present day appears to be that the youth who wishes to become an up-to-date engineer and have a successful career in the profession, having reached matriculation standard at school, should preserve the continuity of theoretical study and proceed at once to the university or college for two or more years. In support of this opinion, though it is encroaching on the subject of another note to this conference, I quote from Mr. Ellington's presidential address to the Institution of Mechanical Engineers in March, 1911:—

"I have always felt that the first eighteen months was more or less wasted, and that that period should have been spent at college. I hold strongly the opinion that it is best for the majority of youths who are about to commence their engineering training to go to college on leaving school."

Opinions of well-known engineers on those lines will have the effect of sending a still greater number of youths to college before entering on their practical training.

Recommendation No. 13 of the 1906 report says:—

"The committee reaffirm the conviction, expressed when they issued their inquiry, that the sympathetic assistance of employers is essential to improvement in engineering education and training."

And, as bearing on the same subject, the following is taken from the introduction to Mr. Zur Nedden's excellent book on workshop practice:—

"It is the many-sidedness of the practical work of the young engineer which, after due cultivation, builds up the 'engineering instinct,' without which no engineer can be successful. Workshop experience necessitates observation, reflection, ability, tact and hard work, and the engineer's success later in life will depend greatly upon the exercise of these faculties in the workshop years."

Many engineering employers, during the last few years, have recognised that systematic scientific education of the modern university and college type is very essential to the future progress of engineering science, and in consequence have extended sympathetic assistance to college students by granting to them facilities to obtain practical experience in their workshops, in order that they might have the opportunity to build up that "engineering instinct" which is so necessary to become a successful engineer. The authorities of the universities and colleges, also recognising the necessity for this workshop period after the completion of the college course, endeavoured, and with very considerable success, to arrange with a number of engineering firms in the industrial centres in which they are situated to co-operate with them in granting college students the privilege of this workshop training. But what strikes one, after a careful study of the apprenticeship schemes as arranged by the college authorities, is that the co-operation between college and employer is not sufficiently definite, as will be seen from the following, taken from the scheme of one of our best organised colleges:—

"Students who desire to serve their apprenticeship with one of the after-mentioned firms must communicate direct with the firm and make their own arrangements."

By this system it is possible, and, as a matter of fact, in my own experience in many instances it has happened, that suitable students, possessing the necessary personality and "engineering instinct," will lose much time, after leaving college, through having been unable to make arrangements to proceed to their practical training at once, and that others will have promising engineering careers blighted by being unable, through lack of influence and means, to arrange for their practical training.

It is an undoubted fact that only a certain proportion of engineering students who finish their college course successfully are suitable to proceed to the workshop for practical training, and the purpose of this note is to suggest an arrangement to ensure that engineering employers shall be asked to give facilities for the practical training of only the most suitable students.

The professors of engineering subjects in the universities and colleges are, as a rule, qualified engineers, who have had considerable experience of works practice, and, in consequence, they are in a unique position, after three years' close contact with the students, to select the most suitable, from the point of view of ability, personality, and grit, to take full advantage of their years of workshop practice, and this method of selection would ensure that want of influence, poverty, or social circumstances, would be no bar to a suitable student completing his engineering training. The selection could be made before the completion of their course, and arrangements made so that no time should be lost.

In the provincial industrial centres it would not seem to be a very difficult problem to arrange for a close and definite co-operation between the engineering employers and the heads of the engineering departments of the colleges on the above lines, in view of the fact that the "civic" universities, such as Manchester, Birmingham, &c., and the technical colleges, such as Glasgow, have been built and highly-equipped by contributions from the local captains of industry, who in this way have shown a living interest in the advancement of scientific training.

The governors of these provincial colleges, in order to

* Read at joint meeting of Sections II. and III., held Thursday, June 29, 1911.

† The second year after graduation, or, as explained in paragraph 1, the third year of practical experience.

‡ Read at the joint meeting of Sections II. and III., held Thursday, June 29, 1911.

have the education thoroughly in keeping with the advance in industrial methods, have adopted a liberal policy in their methods of management; and in order always to be in close contact with the various industries in their district, they have adopted the wise policy of co-opting leading representatives of the various firms to act on the committees of each department.

It would appear, therefore, to be a simple matter for each centre to form a strong committee, in connection with the college, composed of these influential representatives and the heads of the engineering departments.

The duties of this committee would be:—

1. To consider the selection of students made by the professors.

2. To make arrangements with the firms who are willing to grant facilities for practical training to start these immediately on the conclusion of the college course.

3. To arrange that Recommendation 9 of the Report is carried out as far as possible.

4. To induce a still greater number to grant such facilities.

The question of an arrangement on the same lines between the colleges and polytechnics in London and engineering employers is much more complicated and more difficult to solve. In London a number of unconnected colleges and polytechnics came into existence during the latter part of the nineteenth century, due in a great measure to the subsidising of engineering training by the wealthy and generous City Companies, with the result that there is not as yet any central governing body who could act in unison with the various colleges and with engineering employers in London and the provinces to arrange for the practical training of all the most suitable students educated in the London colleges. In consequence of this condition of affairs, each college has had to make its own arrangements, with the result that many capable students have been unable to arrange for their practical training.

The Imperial College of Science and Technology has now been in existence for some years, and has nearly completed its equipment in all departments of science, an equipment which I believe is second to none, and will soon be in a position to produce students of the very highest standard of college training for whom the very best facilities for workshop training must be found. Why should united action not be possible between the Imperial College of Science and the polytechnics? Why should not a central committee be formed, with its headquarters at the College of Science, composed of the heads of engineering departments of these unconnected colleges, and representatives from the London managers of engineering employers and manufacturers, to work on lines already suggested in the case of the provinces? This committee would be able to see that all the most suitable students in London would obtain their practical experience.

There is still another important problem which is worthy of mention in this note, a problem which has arisen in England during the last few years owing to the advance made in general education, and which is now pressing for solution. I am personally most deeply interested in it, and I consider this Conference a most favourable opportunity to bring it to the notice of college authorities and the representatives of county education committees in England. During the last few years, engineering firms in this country have developed a very keen interest in the better education of the engineer apprentice who starts his apprenticeship at sixteen years of age. Every encouragement is given to him to attend evening continuation classes, and several firms allow the best of them to attend classes one or two afternoons a week. The result of this interest is that a certain proportion of these have, by means of such facilities, been able to reach a standard of education which qualifies them to proceed to a fully-equipped college for two or three years of specialised study in the day time. Want of means and lack of an adequate system of scholarships with maintenance allowances, however, prevent them from proceeding further in their ambition.

These apprentices, trained in this manner, are a very valuable asset to the nation, and I would suggest to the Education authorities that they should adopt a scheme whereby the best of them would derive the benefit of systematic scientific education in the day time at one of the fully-equipped colleges. The organisation of such a scheme must ensure that poverty or social circumstances shall not prevent access to the highest forms of training that the community can provide.

SECTION III.—PRACTICAL TRAINING.

*The Relation of Practical Training to College Study.**

By Professor ARCHIBALD BARR, D.Sc., M. Inst. C.E.

DISCUSSIONS on the training of engineers no longer turn upon questions as to the value, on the one hand, of education in those branches of science which deal with the properties of materials and the physical laws that condition the work of the engineer, and on the other, of actual contact with and participation in engineering practice. Various topics are set down for consideration at this Conference, but the terms in which they are defined presuppose an agreement that both education in science and practice in the carrying out of work are necessary parts of any general system of training for those entering the profession.

Our immediate subject for discussion naturally divides itself into two parts:—(1) the relation—or it may be the contrast—between the two branches of the engineer's training in kind; (2) the relation in respect to time.

The nature and the mode of attainment of a suitable practical training will be discussed under other sections, but the present may be the most suitable opportunity for considering how the time spent in college can best be employed.

In defining the topics with which the Conference is to deal the council has used the words "education" and "study" in referring to college work, and avoided the terms "instruction" and the much-misused expression "technical training." This is as it should be. The end to be kept in view in a college course is the education of the student, and the result is to be measured not by the amount of detailed knowledge he has gained, but by the extent to which his mind has been developed, and by the insight he has gained into the principles underlying successful practice. The alternatives before the colleges are: (*a*) the offering to the student, in the limited time at his disposal, of a general course of study that may form a basis for practice in any department of our wide profession; or (*b*) the provision of a number of courses, from among which the student may select the one that appears to bear most directly on the particular branch he expects to follow.

If I may state my own view, it is that little specialisation should be attempted, if for no other reason than that the young engineer, if he has the elements of success in him, cannot foresee the trend his career will take. The best college course is the one that is most educational, and this will be the course that gives the student the broadest outlook upon his profession. It need deal little with the details of specialised practice; these can best be learned in the workshop, the field, or the drawing-office. Men who are successful in engineering practice seldom follow in later life the particular line of work in which they have been trained; and of two men, one of whom has a thorough grasp of general principles, and the other a knowledge only of the details of one branch—however intricate that knowledge may be—the former is in a much better position to take advantage of such opportunities of advancement as may come within his reach. Moreover the conditions of practice, even in one limited sphere, are constantly changing. The college course should, then, be on broad lines, and should aim at giving the student a thorough grasp of general principles, illustrated by examples of their application in various branches of practice.

The question as to the order in which the two sections of the engineer's training should be pursued is also one that admits of no general answer. What will be best for one man may not suit another. Much depends upon the special circumstances of the pupil in regard to his mental qualities and attainments, the facilities he can command for study, and the opportunities he may have for securing practical training when he desires to enter upon it. Moreover, other things being equal, a man who has had a practical training is better able to benefit by a course of study in engineering science; and, on the other hand, a man who has had a sound training in science is in a better position to take full advantage of his apprenticeship or pupilage. But he cannot have it both ways. In favour of the college course being taken first, and pupilage or apprenticeship entered upon after graduation, it may be urged with good reason that by the continuity secured in the pupil's education, the danger of his losing the habit of systematic study, and his grip of what he has already learned at school, is avoided. Further, he will enter on his practical training with his mind disciplined and developed by his study of science, and experience comes most quickly and with most lasting effect to one who can place each item as it presents itself in its proper place in a connected system of knowledge based upon general laws, the workings of which he has learned to recognise.

Further, if the college course is entered upon after practical training is completed, the pupil severs his connection with the firm under whom he has been trained, and he may have to make a fresh start in life when he leaves college.

In favour of practical training following directly after school, it is urged, also with good reason, that the initial stages at least of apprenticeship or pupilage should be got over at an early age. A man man who has gone through a complete course of study in a university or technical college will necessarily have reached an age at which he may take less kindly than the school-boy will to the drudgery of initiation into the routine of practice in the workshop or the office. Again, the man who takes his apprenticeship or pupilage first, goes up to college with such a knowledge of his needs as will enable him to appreciate the value of what is offered for his assimilation. Furthermore, any lengthened course of study, without the correcting influence of experience of the requirements and limitations imposed by the conditions of practice, is liable to become altogether too "theoretical" in his outlook and his attitude of mind.

The disadvantages of postponing the college course to a late period in the pupil's training can be mitigated, to some extent, by private study or attendance upon evening classes, during the period of actual training, and good results follow in the case of men of special ability and perseverance; but the time and energy that can be at the pupil's disposal for evening work are limited compared with those he could command in a complete curriculum of day study at a university or technical college.

There is, then, something to be said on both sides, but as both systems cannot be followed, the best that can be done, in order to have in large measure the benefits of both, appears to me to be to adopt what has been called the "sandwich system."

It is sometimes assumed that the advocates of the sandwich system commit themselves to a particular disposition of the slices of study and practice and some definite quantitative relationship between their volumes. No hard-and-fast specification need be made. What is here meant is any arrangement that permits of college study being begun at a time not too distant from the close of the pupil's school-days; that provides that during the later part of his studies the student will have the benefit of some measure of experience in the actual conditions of practice, and that ensures that the latter part of his practical training will be taken after he has had his mind disciplined by a course of study in pure and applied science. Whether a short period of practical work—say a year or so—should immediately follow school, or, on the other hand, the first year course at college (in pure science) should come first, depends, in my opinion, upon the circumstances of each pupil as regards his state of preparation for higher studies and the facilities he can command for entering upon practical work when he desires to do so. I do not think any rule should be laid down.

Many objections have been raised to the sandwiching of study and practice. One is that the usual college session of eight or nine months leaves too thin slices of practice if the college course is taken in consecutive sessions. I agree with this view. When the system is adopted the college session should be limited to six months, as is done in some universities and colleges. Another objection is that engineering firms will not be disposed to take men on for six-month periods, with breaks of equal duration. Any pupil who finds it impossible to get entry to practical work on these lines must take his training in some other way; but hundreds of students do find openings that permit of thus sandwiching their training. The system is not new; it is, indeed, the oldest followed by university students of engineering science; it has been adopted by generations of students since the Glasgow Chair of Engineering was founded in 1840, and my own experience during the forty years I have been connected with its working has given me the firm conviction that it affords the best kind of training for the great majority of men entering the profession.

In conclusion, I would plead that the institutions should give a latitude in the systems of training that they will recognise. Let it not be forgotten that no two of the men who have made our profession what it is have entered it by the same path, and that many of the most eminent of them have had no training that would to-day be recognised as a normal one, either in respect to education or to practice. Men differ in natural qualities as much as wood and stone and steel, and the tools and treatments that will fashion a useful product out of one, may make a sorry job of it when applied to others. Let the system of training differ in different districts, if needs be, and let the courses of study offered by the colleges vary in substance and in method. We cannot dictate to members of the profession the terms and conditions on which they will take apprentices or pupils, and it will be destructive of much that is best in the influence a teacher may have on his student if he is forced by any detailed regulation to work upon lines inconsistent with his bent, and contrary to the dictates of his own experience. There is need in the profession for men of widely different qualifications: let us not aim at turning out our recruits like so many forgings stamped in one set of dies.

*The Relation between Practical Training and College Education for Engineers.**

By Professor HENRY LOUIS, M.A., M. Inst. C.E.

IN the discussion of this question, it seems advisable to determine in the first place what are the points upon which there is practically a general agreement. All agree, I believe, that every engineer must have practical training, and though there may be still some who hold that when he has this all knowledge of theory is superfluous, I venture to say that no engineer of any eminence holds that view to-day, so that I shall commence with the assumption that training in both theory and practice is generally considered as indispensable to the engineer. As to the relative amounts of knowledge of either branch, and the character of such knowledge, there is a wide divergence of views. Possibly all will agree that there is nothing that has a greater influence upon the success of an engineer's career than the ability to deal with men. This is in many cases an innate ability, though it can undoubtedly be cultivated and developed; it is often said that one of the drawbacks of a college education is that it does not call out these traits of a young man's character, but in my opinion this charge is due to an imperfect appreciation of the scope of a college training. Mere attendance at lectures and laboratories will certainly not do much towards attaining this object, but it must be remembered that attendance at lectures and laboratories is only a part of college life. In the relations between teachers and students, and still more in those among the students themselves, a British college forms one of the best schools in existence for teaching tact, good temper, honesty of purpose, and that sportsmanlike sense of fair play which form the best foundation for dealing with men of all classes. Participation in college societies, intellectual and athletic, as well as the large degree of self-government allowed to students' representative bodies, tend to foster a sense of order and responsibility, and to develop a power of administration, which are of great value in after-life. Again, it has been sometimes urged that our colleges fall short in the matter of discipline, that in a works a young man will more readily acquire the all-important habits of punctuality and promptitude which in a college are not always inculcated with sufficient strictness. For this charge there may, I believe, be some foundation, but the defect is in no way essential to a college system; the remedy once pointed out is easy to apply, and I have

* Read at meeting of Section III., held on Thursday, June 29, 1911.

* Read at meeting of Section III., held on Thursday June 29, 1911.

every confidence that the importance of its application is becoming more and more generally recognised. Indeed, I think it may fairly be argued that a college training is of quite as much value in the development of character as in the acquisition of knowledge.

There is no portion of the engineer's training upon which greater diversity of opinion exists than there is in respect of the manual training that should go towards making up the education of an engineer, and, curiously enough, this diversity is specially characteristic of the various branches of the engineering profession. Mechanical engineers, and to a lesser extent also electrical engineers, insist that a lengthy apprenticeship to the manual portion of the trade is indispensable, whereas the "Civil" engineer looks upon it as wholly superfluous. The one insists that the pupil must learn how to use the hammer and the file, the other sees no reason why he should touch the shovel or the pick. For my part I cannot see why, if a man can build a bridge without being a skilled riveter, he must be a skilled fitter before he can build the engine that is to run over it. Still more curious is the anomaly in the two closely cognate branches of mining engineering: most metal miners look upon practical acquaintance with the use of the miner's tools as an important part of the mining engineer's training, whilst the coal-miners hold that any such manual skill is entirely unnecessary. Personally, I am inclined to think that this profound faith in the necessity of manual skill is to a great extent a piece of fetishism, a survival of the old apprenticeship system, which used to be the only avenue leading into any branch of the engineering profession. I will not go so far as to say that manual skill is useless to the engineer, but I am convinced that most of us rate it far too highly. It is pretty clear that the object cannot be the acquisition of manual skill for its own sake, but rather for the purpose of gaining familiarity with the properties and working of the materials which the student will have to employ for constructional work, though I should be hard put to it to explain why an architect should not be compelled to serve his time as a stone-cutter on precisely the same principle.

Where views as to the need for manual work diverge so widely it is hopeless to attempt to lay down any rules generally applicable to the training in such work. This, however, does not apply to the whole of the subject of practical training, of which manual work is only one, and probably not the most important, part. If it be granted that actual technical experience amongst the men who are engaged in doing engineering work is essential, it will, perhaps, be fairly admitted also that the college is not the place to attempt to acquire such experience, and that any attempt to imitate works practice in a college is necessarily bound to result in failure.

A college is the place to learn principles, and not practice. If this be admitted, it is not a very long step further to argue that the knowledge of principles ought to precede the study of their application, and that therefore college teaching should precede, and not follow, practical training. Whilst I hold this to be true, I also believe that many teachers will concur in my view that a moderate amount of practical training may be useful in the later stages of a college career, as giving more definiteness to the student's work, and showing him more clearly the objective towards which his theoretical studies should be directed.

This is, broadly, the conclusion to which my experience is leading me. I do not find that the sandwich system in its true form—six months at college and six months in works—is satisfactory upon the whole, and think that it frequently results in both college work and the practical work being badly done. On the other hand, after three or four years passed in the workshop, a young man usually finds it difficult to come back to his studies, and is not likely to make as good progress as if he had come to college straight from school. Of course, every teacher can quote numerous cases of highly successful students trained in one or other of these methods, but I am dealing here with generalities, and not with the more exceptional cases. I am inclined to think that the method now generally adopted for coal-mining students is one that embodies the soundest general principles; these students have often seen a little coal-mining or practical engineering of some kind before they come to college; they take a three years' college course, spending their long vacations at a colliery, where they are usually put to going underground regularly with one of the officials, and thus getting accustomed to seeing how work ought to be carried on, whilst they also spend a portion of their time in the drawing-office and the colliery offices. After taking a college degree, the law insists that they shall have three years' practical experience underground before they are allowed to take the examination for a certificate as a colliery manager.

The above general system, suitably modified, would probably be applicable to all branches of engineering. Directly on leaving school, I would have the engineering student pass his matriculation examination, then go to a suitable works (using this word in its widest sense) for three to six months, then come to college for his three years' course, returning to the same, or to a different works, for two or three months during each long vacation, and then finally serve a two or three years' apprenticeship. I think that any manual work is best done in the time between school and college. Many teachers will probably support my view that an engineering degree course should extend over four years, instead of three as at present—a view that I have advocated for many years, and to which I find that general opinion is now gradually trending. Every branch of engineering to-day has assumed a high degree of complexity, and I do not think that seven years is too long a period to devote to the acquisition of the necessary technical knowledge, whilst I venture to think that this is best divided up in the manner I have indicated.

---

*Workshop Training as a Preliminary to Practical Training in other Branches of Engineering.**

By JOHN ALEXANDER BRODIE, M.Eng., M. Inst. C.E.

IN introducing this subject I have thought it well to assume that the youth about to take up engineering as a profession is of average ability and circumstances, about 17 years of age, that he has had a good general education, a superior mathematical training, and preferably an experimental knowledge of one science subject. He should also have been trained to think for himself, to express his views clearly and concisely in speech, and to report in writing on any matter which may be put before him. If he has been accustomed to act as schoolboy captain or to work to the orders of his captain in sports and athletics, so much the better, and he should be encouraged to keep up his connection with healthy outdoor sports.

By some it is thought that training in school and college workshops is of considerable value, and whilst this is, no doubt, better than no training in workshops at all, I take the view that workshop practice, to be of real value to the engineer who proposes to advance in his profession, must be conducted under commercial workshop conditions in which considerations of time, money, discipline, organisation, and enterprise are factors of importance.

At the age named the youth should have sufficient strength of character and physique to take care of himself in the workshop atmosphere, and he is yet sufficiently young to adapt himself to the dirty conditions of work, the muscular exertion, and the somewhat rough-and-ready manners of the workmen with whom he must learn to work on a friendly footing if he is to obtain their help and assistance.

Probably all experienced engineers are to-day agreed that a period of practical training both in shops or works and drawing-office is of undoubted advantage to the engineer, much increasing the value of his services as an assistant, and adding to the weight of his advice and opinion at a later stage in his career. Important points for consideration are: (1) The class of workshop he should enter; (2) the class of work most likely to be helpful in his future career; and (3) the length of time which can be given to works and drawing-office training.

As the result of experience I am firmly convinced that the best type of workshop is one in which the materials used and the classes of work done should be as varied as possible. If repair and maintenance work is done so much the better.

It will generally be found that in a comparatively small works the youth's ability will be more fully utilised, the necessity for quickness and accuracy more quickly brought home to him, and he will also have the advantage of being more directly under the eye of the master.

As against this view, it is often considered that training with a well-known firm more than counterbalances the advantages obtainable in a small general workshop, and it must be admitted that training in a great works, especially if followed by a pupilage or subsequent experience in one of the best offices, is still looked upon as a good introduction to the profession, particularly for those desirous of taking up work of a public character.

For the youth who does not propose to remain in the workshop it is not, I think, so necessary that he should learn to equal the workman in his knowledge and ability to execute any one class of work as that he should acquire an intelligent knowledge of the processes and methods of treatment of the various metals and other engineering materials.

Perhaps of greater importance than anything else is the ability to form a correct opinion of the capability of the men in a workshop, a knowledge of their methods of thought and work, a study of the systems adopted to get work pushed through to completion, and generally such knowledge as will enable him to handle men advantageously when occasion requires.

The importance of obtaining some practical experience in a works' drawing-office should on no account be overlooked, as efficiency and speed as a draughtsman, combined with some ability to design, has been the first step in the rise of many men who have advanced to the higher positions in the profession.

It should also not be forgotten that the young engineer may at any time be called upon to proceed abroad to take charge of works under conditions wholly unknown in this country, and, speaking from my own experience, I can say that the knowledge of workshop practice in materials such as the metals, wood, stone, and cement, together with drawing-office experience, have been of the greatest assistance in settling points of importance when away from the experienced and helpful friends who are generally available for consultation in this country.

With regard to the period of time which should be given to practical work at this stage in the young engineer's career, I would, wherever possible, allow for three years in works and drawing-office, especially if, as in many cases, it is necessary or desirable that the youth should, on the completion of the additional period of study, desire to get a start in an office or works in this country.

It is my experience that a youth with three years' practical workshop training as a preliminary to his college education would have much less difficulty in getting a useful start in the profession than the youth who only had a college training. In the one case, having obtained his degree, he is probably well worth starting at once on a small salary and should pay his way on any class of work. In the other case, a considerable time will usually elapse before he settles down to real work, and it does occasionally happen that the university man's estimate of his own value as an assistant is not reached in practice for a considerable period.

What I understand to be the practical objection raised to the acquisition of practical experience before taking a college course is that young engineers are generally unable to keep up their ability to study or to improve their technical education during the practical training in workshops. I number amongst my friends a large number of men who obtained most of their theoretical training whilst working the full workshop and drawing-office hours at a time when the facilities for acquiring such knowledge were not by any means so general as they are to-day. I have, consequently, little sympathy with young engineers who cannot do so, or with those who think it necessary that young engineers should work a reduced number of hours in the workshop so that they may be able to give greater time to study and to improve their theoretical work. It used to be, and is, I believe, still, the almost universal workshop practice not to give important work to short-time men, and, therefore, a youth working short time is seriously handicapped in obtaining practical experience of value.

Short hours should not be allowed as a general practice, and though it may be a good thing to allow additional time for study, this should be within the works or under some form of control. I am aware of many cases in which these well-intentioned allowances of time for study have been abused, and I believe that even after a day's hard muscular work mental training may with advantage be continued, especially during the winter months, when little in the nature of healthy outdoor exercise is possible.

I can perhaps best conclude these remarks by relating an experience of my own when being shown over a Continental works by a young engineer under 21 years of age. He conversed quite easily with me in English, and from my inquiries I was satisfied that he had an excellent knowledge of the technical processes and of the results obtained in the works which he was showing me over. I also found he had a good knowledge of Spanish, and I understood that he was equally acquainted with three other languages in addition to his native language. I found he was a college student studying for his Doctor of Science degree. In his spare time he was being paid to conduct the foreign correspondence of the firm. I also found that a director of the works in question was a teaching professor at the university, and on consideration I came to the conclusion that both in the interests of the students, the manufacturing processes, and the professor himself, the arrangement appeared a good one.

It appears probable that if our youths of to-day cannot or will not stand the strain of the severe training which has in the past given good results, they will probably have to take a position behind those who are prepared to do so. It may on the whole be better that they should take up work better suited to somewhat easy-going methods, and it cannot be doubted that there are many lines of life in which young men can more easily and quickly acquire both money and position than in the engineering profession. Even with hard work, deep thought, foresight, organising power, a clear grasp of the situation, determination, and strong common-sense, success in engineering is not always assured.

* Read at meeting of Section III., held Thursday, June 29, 1911.

---

*Workshop Training as a Preliminary to Practical Training in other Branches of Engineering.**

By JOHN MITCHELL MONCRIEFF, M. Inst. C.E.

IN the consideration of the training of students entering the engineering profession without intending to follow the purely mechanical branches, there is no question more frequently raised than that of the desirability, or otherwise, of a training in the workshops of a mechanical engineer. Those engineers who in the past have had the benefit of such a training generally hold that it has been of the greatest benefit to them in their subsequent career.

It will be of use to consider the question in the following form:—What ought the student to learn during such a period of workshop training, and how does the knowledge to be gained during this period bear upon subsequent practical work in other branches of engineering?

In dealing with this question it is only possible to touch upon some of the more important points in an introduction to a discussion.

(1) The student will, or ought to, learn the value of discipline and the necessity of order, punctuality, and continuity in work.

(2) He will acquire a personal knowledge of the various materials used in the manufacture of machinery. This personal knowledge is entirely different from anything which can be obtained by any amount of reading or laboratory work. He will actually feel the materials as he works with them, and his knowledge not only of what can be done, but of what can reasonably be done with them, will be greatly extended.

(3) He will learn the use of hand and machine tools, and how much can reasonably be done in a given time with their aid under ordinary commercial working conditions. I do not mean that the student will thus acquire a complete knowledge of working costs, but he ought insensibly to develop that most valuable faculty of being able to judge whether this or that method of work is the more economical, and as to whether it is suitable to the materials being dealt with.

(4) He will see the order in and foresight with which work is distributed throughout the shops so as to ensure

* Read at meeting of Section III., held on Thursday, June 29, 1911.

that the whole, though composed of innumerable units, shall all work to one common end with due regard to economy.

(5) By working at the vice, the lathe, the pattern-makers' bench, in the smithy, in the foundry, or in the boiler-shop or bridge-yard, he will learn the various processes through which work passes, and he should become imbued not only with the scientific side, but, at this stage, still more importantly with the commercial side of engineering work.

(6) By working side by side with workmen he will have the opportunity of studying their characters and modes of thought. He will learn what a man may reasonably be expected to do, and also what it would be foolish to require of him. My personal experience is that workmen have a keen scent for a man who has worked alongside of them and is qualified to sympathise with their difficulties or justly to condemn their deficiencies. The influence of an engineer who has had such personal contact is immeasurably superior to that of one who has merely had a bowing acquaintance with labour.

The value of such personal contact is not confined to influence over workmen; it extends to subsequent business life when dealing with experienced engineers, whether consulting or manufacturing, and especially the latter, who not seldom make the criticism that such and such an engineer "has no real practical knowledge of the work. He merely is a paper man."

(7) The student in the works should also begin to learn some of the limitations of the application of science to practical work. It is, or ought to be, common knowledge that that which on the surface appears scientifically desirable may be practically foolish and wasteful both of time and money.

(8) If the student's mind be of true engineering bent he will unconsciously acquire a knowledge of the relative proportions of details of machinery and structures, and his eye and mind will be trained by the daily study of work which embodies the accumulated experience and extended study of others who are preceding him in the same walk of life.

(9) A period of training in the practical side of mechanical engineering will impress on the student the great importance of accuracy. My own experience has been that if a youth be trained originally to appreciate the importance of a hundredth of an inch, he can easily be trained subsequently to deal with coarser measures, such as cubic feet or cubic yards. On the contrary, a man whose early training has been in cubic yards generally scorns any attempt to get him to think in hundredths of an inch, however important that small dimension may actually be.

(10) By working actually at vice or bench or machine in a dividend-earning concern, the student is brought into personal touch with the money-value of time, labour and plant, and is forced to realise that without full recognition of such money-value, success in everyday life will not be attained.

(11) A thorough grounding in all this valuable experience and knowledge is to be gained within the gates of a mechanical or structural engineering concern, and all within an area of comparatively limited extent.

No subsequent training on large works of construction can so fully and quickly and efficiently supply all the desiderata of training which have been outlined above.

(12) What important engineering work was ever carried out without the use of mechanical appliances?

Let us assume that a young man is placed as a junior assistant on the construction of docks, bridges, harbour works, or any large work. The first things which force themselves on his notice are locomotives, pumps, cranes, concrete-mixing machines, dredgers, piling-machines, sawmills, power-houses, air-compressors, electric plant, and machinery of great variety. He has also to deal with workmen of various kinds, skilled and unskilled.

All these are spread over a considerable area, and he will, in all probability, have but little opportunity of obtaining more than what has been described above as a mere bowing acquaintance with any one of them until troubles arise, as they invariably do, demanding that experience which ought to have been acquired by actual personal contact with men and things.

(13) Further, what can be expected of a designer of machinery, ships, bridges, structural steel and ironwork, water-works, gas-works, electric plant, or any other of the varied productions of engineering, if he has had no mechanical training? The answer may be given in the words of a works manager, who criticised the design of some of the details of dock-gates which his firm were carrying out to a consulting engineer's designs, as follows: "The work might almost as well have been made of solid silver."

---

*Workshop Training as a Preliminary to Practical Training in other Branches of Engineering.**

By Professor JOHN JOSEPH WELCH, M.Sc., M. Inst. C.E.

IT is, I take it, admitted that a practical course of considerable duration under commercial conditions is necessary to the complete training of a student who desires to become fully equipped for entry into any one of the branches of engineering, although, possibly, in these days the fact requires somewhat more emphasis than was formerly necessary. Scott-Russell, writing in 1867 concerning the then newly-formed Royal School of Naval Architecture at South Kensington, stated that the question as to whether a theoretical or practical training best fitted an engineer for his profession had before then been the subject of much debate, and had been decided generally in favour of the practical course, a fact that Mr. Ellington also pointed out in his recent presidential address to the Institution of Mechanical Engineers. In the paper already referred to, Scott-Russell affirmed his conviction that both scientific and practical training were essential, and pointed out how this was attained in the arrangements made at South Kensington. Since that time much has been done to emphasise the need of proper scientific training, and few will be found to question the wisdom of the Council of this Institution in insisting upon a high standard of theoretical knowledge in those desiring membership. Also, and to at least an equal degree, their emphasis upon the need of practical training commands approval, and the unanimous opinion of the important committee, which reported to this Institution in 1906, that engineering training must include several years of practical work, as well as a proper academic training, is one which is not likely to be seriously challenged. The committee recommend that the practical training should, in general, commence with at least a year's work in mechanical engineering workshops, even for those who do not intend specially to devote themselves at a later stage to mechanical engineering; and the desirability and feasibility of this preliminary workshop training are the subjects which it is desired to open up for discussion by means of this note.

In considering the latter subject the point of view of the employer must always be borne in mind, for, however desirable the training may be, it is the employer alone who can make it possible; and whole-hearted co-operation between the employer and the engineering colleges is essential if the best results are to be obtained, and if the course recommended by the committee is to be generally adopted in practice. The committee, indeed, recognised that difficulties might be encountered in carrying out their suggestion, and anticipated that employers might consider the arrangement objectionable in their interests. This anticipation has not been falsified by experience, and it is known that in many cases objection has been raised to the apprentice leaving for college just at a time when he was becoming of distinct value to the employer.

In attempting to appraise the value of this preliminary training it seems convenient to consider separately the case of those students who intend following up what may be summarised as general mechanical engineering, and those who intend to devote themselves to branches of engineering in which machinery is not so extensively employed.

Dealing with the former case first, the student may, immediately after that period, desire to take up his college work, or he may continue his practical training in an office. In each case he would find the introductory workshop course helpful. Most colleges provide a course of study during the first year which is common to all sections of engineering, and the lectures on, say, applied mechanics are more easily comprehended by those students who have seen at close quarters and handled the machines and details taken for the illustration of principles. It goes without saying that these students find one great advantage of the early training in the ease with which they can understand the allusions to technical details in the specialised courses.

If, on the other hand, the student after his preliminary course goes into an office, he will, in all probability, be early introduced to specifications of work, and here again he will find his early experience useful in understanding the terms used. Or he may be employed drawing out details and fixing sizes, and his work at the shop will enable him to appreciate dimensions and proportions much better than he could hope to do without that experience.

Further, the lad who enters the works at a comparatively early age gets into closer contact with the workman, and the workman seems more willing to teach him at that stage than after the college period is passed. This close association in the works enables the student to gain the point of view of the artisan, a point of some importance to those who may subsequently be placed in charge of men. Then, again, this immersion into a commercial atmosphere immediately after leaving school comes as a pleasant break in his scholastic studies, introduces him to new interests, and enormously widens his outlook by the time he is called upon to take up his college work; and he does so with a better appreciation of the goal towards which he is tending than is possible to one without such preliminary training. It should, perhaps, be added that this early workshop experience is occasionally useful in convincing some young men who thought of taking up engineering as a profession that they had mistaken their vocation, and they have been able to select some more congenial sphere without any important loss of time. The discovery of unfitness would probably not have been made so early had the college training been taken first.

For all these reasons, then, it is considered that an introductory workshop course for those intended for the general mechanical engineering profession is of distinct importance; and it is significant that a similar course is now insisted on for German shipbuilders and engineers before taking their theoretical course at a high school, although former students were allowed to get their high-school training without such practical experience.

The length of training recommended by the Committee of this Institution seems adequately to meet all requirements; and it has been found that periods very materially in excess of one year, interposed between school and college, tend to make it difficult for the student to pick up again the threads of his interrupted mathematical and other theoretical studies.

Considering next the case of "Civil" engineers and others not so closely associated with the design and care of machinery, one speaks here with some diffidence on account of less intimate knowledge of all the conditions; but, remembering the increasing use of plant and machinery of all kinds in all branches of engineering, it seems that in this case also a preliminary workshop training must be of very distinct use. It will be obvious, without special reiteration, that some of the advantages claimed above are equally relevant to the "Civil" engineer. It would help him in his early college course and in his subsequent office work; and he would probably gain from the use of tools during this period a better idea of the mechanical properties of materials than he is likely to obtain at any subsequent stage.

The early training in the regularity and under the discipline inseparable from a commercial establishment is not to be lightly esteemed, and may easily influence the student for good throughout his subsequent career. It is arguable, however, that in the case considered, the preliminary course could be somewhat shortened as compared with that for the mechanical engineer, and that from six to nine months would furnish all the experience needed.

As already indicated, it is known that many employers do not favour this short introductory course preparatory to college training: and some question the wisdom of this latter training altogether. It has been stated that many students, who originally went to works with the idea of proceeding to college after twelve months, have been persuaded to continue their practical training to the completion of their apprenticeship, and to rest content with such theoretical knowledge as they could gain at evening classes after their day's work. On the other hand, there are other employers fully persuaded of the wisdom of this introductory course, and who give the necessary facilities.

It is hoped that employers will freely give the Conference the benefit of their experience in this important matter, to the end that the young engineer may receive the most perfect practical and theoretical training which experience can devise, to fit him for duties which seem ever increasing in complexity and responsibility.

* Read at meeting of Section III., held Thursday, June 29, 1911.

FOREIGN ENGINEERING PROJECTS.

WE give below several notes of colonial and foreign engineering projects. Further data concerning them can be obtained from the Commercial Intelligence Branch, Board of Trade, 73, Basinghall-street, E.C.

Canada: H.M. Trade Commissioner for Canada reports that tenders are invited by the Board of Commissioners of Montreal for the construction of the final filters and appurtenances in connection with the new city filtration works. The final filters are to be of concrete masonry, having a net filtering area of about six acres, and a height of from 20 ft. to 25 ft. Electrically-worked machines for cleaning the filters, apparatus for heating and ventilating them, and cast-iron piping and valves for conveying and controlling the water, are to be furnished. Sealed tenders, on the proper form, marked "Tender for Final Filters and Appurtenances," will be received at the office of the Board of Commissioners, City Hall, Montreal, up to noon on July 13. It will be observed that the time for the receipt of tenders is short, and this intimation will only be of use to those firms having agents in Canada who can be instructed by cable. A deposit of 65,000 dols. (about 13,350*l.*) is required with each tender. With reference to the proposed dredging of St. John Harbour East (Courtenay Bay), the Imperial Trade Correspondent at St. John, New Brunswick, reports that tenders are invited by the Department of Public Works, Ottawa, for the construction of a breakwater, and of wharves, the dredging of a channel and basin, and the construction of a dry dock and ship-repairing plant of the first class. Sealed tenders, on the proper forms, marked "Tender for Harbour Works in Courtenay Bay, St. John, N.B.," will be received by the Secretary, Department of Public Works, Ottawa, up to 4 p.m. on August 10. A deposit of 500,000 dols. (about 102,700*l.*) will be required with each tender. The *Daily Witness* (Montreal) publishes a notice inviting tenders for the construction of a section of about 185 miles of the Hudson Bay Railway—viz., from Pas Mission to Thicket Portage. Tenders, on the proper forms, marked "Tender for Construction of Hudson Bay Railway," will be received at the Department of Railways and Canals, Ottawa, up to 4 p.m. on August 1. Each tender must be accompanied by an accepted bank cheque for 200,000 dols. (about 41,100*l.*). The *Witness* also states that tenders are shortly to be invited for the construction of the Halifax and Eastern Railway, and of the line round the north shore of the Bras d'Or Lakes in Nova Scotia.

Switzerland: H.M. Vice-Consul at Zurich reports that tenders are invited by the Swiss Federal Railways Administration for works in connection with the construction of a tunnel 8135 m. in length between Tecknau and Olten. Tenders, marked "Tunnel du Hauenstein," will be received at the Direction Générale des Chemins de Fer Fédéraux, Berne, up to July 31.

Mexico: The *Diario Oficial* contains the terms of a contract under which Mr. William Hann McLachlan is granted a ninety-nine years' concession for the construction of a railway in the State of Mexico—viz., from Toluca to Caleras, passing close to Villa del Valle. Six years are allowed for the completion of the line, and five years are permitted during which construction material may be imported duty free.

Argentine: With reference to the contract for port works in the Military Port at Bahia Blanca, H.M. Consul at Buenos Aires reports that the successful tenderers were Messrs. Dickerhoff and Widman, Limited, of Nuremberg, and Mr. F. H. Schmidt, of Altona. The *Boletin Oficial* contains a decree approving the plans, drawn up by the General Directorate of Railways, for the construction of a section, 50 miles in length, of the Puerto Deseado-Lago Buenos Aires line. The cost of the work is estimated at 1,624,000 pesos gold (about 325,000*l.*), which amount includes the rolling-stock,

THE WORKS OF MESSRS. BROWN, BOVERI, AND CO., BADEN.

AMONGST the important engineering establishments to be inspected by the members of the Institution of Mechanical Engineers during their summer meeting in Switzerland this month, the first to be visited will be that of Messrs. Brown, Boveri, and Co., at Baden. The firm named was established as a private company in 1891 by

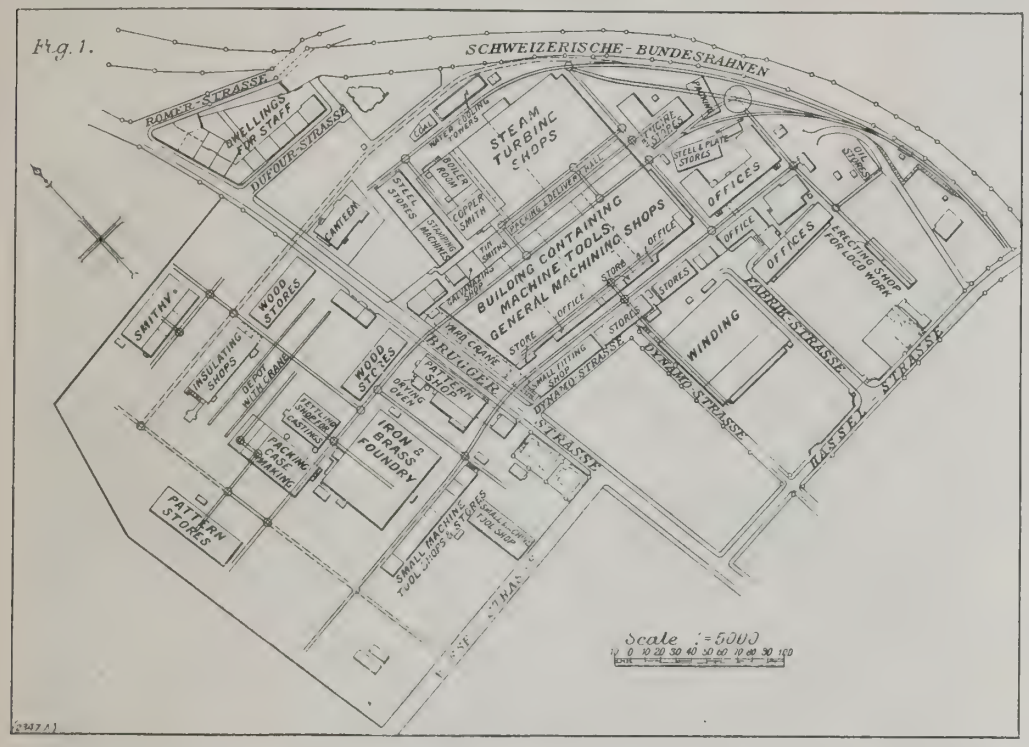

FIG. 2. GENERAL VIEW OF WORKS.

many, and this was also transformed into a share company in 1900. During 1902 they founded the Compagnie Electro-Mécanique at Le Bourget, near Paris, and in 1904 the Tecnomasio Italiano Brown, Boveri, Milan. This latter was enlarged in 1908 by amalgamation with the Unione Elettrotecnica Italiana and Gadda and Co. Branch establishments were then founded at Christiania in 1905, in London during 1906, and at Vienna, Budapest, and Rotterdam in 1910. In 1910, also, Messrs. Messrs. C. E. L. Brown and W. Boveri, and suitable works were built by them at Baden, near Zurich. At these works they manufactured almost exclusively electrical machinery up to the beginning of 1900. In 1900 the company was transformed into a share company with a capital of 12,500,000 francs (500,000*l.*), that undertook the manufacture and further development of the Parsons steam-turbine. In the early days of the company—*i.e.*, in the years 1892 and 1893—the total number of people employed by them was under two hundred, whereas at the present time the Baden works have a total staff of 3700. Taking into account their works and agencies at Baden, Mannheim, Paris, Milan, Christiania, London, Vienna, Budapest and Rotterdam, Messrs. Brown, Boveri, and Co. employ a total staff of over 10,000.

As far back as 1898, Messrs. Brown, Boveri, and Co. established a branch at Mannheim, Germany, and this was also transformed into a share company in 1900. During 1902 they founded the Compagnie Electro-Mécanique at Le Bourget, near Paris, and in 1904 the Tecnomasio Italiano Brown, Boveri, Milan. This latter was enlarged in 1908 by amalgamation with the Unione Elettrotecnica Italiana and Gadda and Co. Branch establishments were then founded at Christiania in 1905, in London during 1906, and at Vienna, Budapest, and Rotterdam in 1910. In 1910, also, Messrs. Brown, Boveri, and Co. took over the share capital of the Elektrizitäts-Gesellschaft Alioth, München-stein-Bâle, and also that of the Isaria-Zähierwerke, Munich. Both these works now practically belong to Messrs. Brown, Boveri, and Co.

The works of the firm at Baden, which will be visited by the members of the Institution of Mechanical Engineers on Monday, the 24th inst., occupy at the present time an area of 380,000 square metres (450,000 square yards), of which 45,000 square metres (53,800 square yards) is covered by the various shops and buildings. The accompanying plan, Fig. 1, shows the Baden works as they now stand.

Before entering into a detailed description of the sundry departments, a few general particulars may here be given. All the bays, forming the different shops, are served by overhead electric travelling-cranes, forty-two in number, with lifting powers ranging from 2 to 30 tons, these cranes being driven by 126 electric motors. The various shops contain a total of over 1700 machine-tools, among which are a large number of the latest types of American automatic and semi-automatic machines. All these machines are driven, either separately or in series, from overhead transmission shafts through belting, by means of over 320 electric motors developing a total of about 2200 horse-power. The average current consumption for light and power amounts to about 1300 kilovolt-amperes. The current required is supplied by the two hydro-electric generating stations of the town of Baden, and also, in case of need, by the generating station of Beznau-on-the-Aar.

The rapid development of the company is principally due to the high quality and excellent workmanship of their products, and also to the special interest which the firm have taken in alternating-current technics, and the advocacy of the use of alternating current at a time when the practical use of this form of current was new and required development. The firm were also the first to introduce the use of the Parsons steam-turbine on the Continent, and to recognise its great value. Licenses were taken out by them for the greater number of the Continental countries, and they were so successful in modifying the constructional details to meet the demands of Continental practice that the Parsons steam-turbines, as constructed by Messrs. Brown, Boveri, and Co., were the first to replace the reciprocating type of engine in most of the electric generating stations on the Continent.

At first, as is well known, the power of a single unit rarely exceeded 3000 horse-power, but great progress has been made since then, and as an instance of this it may be mentioned that Messrs. Brown, Boveri, and Co. have now in course of construction several steam-turbines of 25,000 horse-power, and have on order, in their diverse works, at the present time, turbines for an aggregate horse-power of 750,000. These large units, and also the large marine turbines which the Mannheim works supply to the German Navy, under agreement with the "Turbina" Deutsche Parsons Marine A.-G., Berlin, are built at the Mannheim works. Their Baden works are laid out more especially for the construction of the smaller and medium-size turbines. They have, however, in hand at the present time at these latter works two large units, one of 18,000 horse-power for Buenos Aires, and one of 25,000 horse-power for the Rheinische-Westfälische Elektrizitäts-Werk, Essen.

Since the date at which they commenced the construction of steam-turbines, in 1900, Messrs. Brown, Boveri, and Co. have built over 1100 such engines, having a total of over 2,700,000 horse-power, distributed among current-generating stations and practically every industrial application, including mining, metallurgy, paper and textile works, marine propulsion, &c. The development

in the use of the steam-turbine for industrial purposes has been assisted in a marked degree by the well-known pioneer work which Messrs. Brown, Boveri, and Co. have done in connection with the design of alternators.

Notwithstanding the fact that the steam-turbine has always been from the very beginning an economical prime mover, strong efforts have been and are constantly being made to increase still further its advantages, and, as a result, important improvements have repeatedly been introduced. Thus several years ago the Parsons turbine of the pure reaction type was fitted with an impulse wheel for the purpose of utilising the very high pressure stages, this improvement embodying the double advantage of keeping the high temperatures out of the cylinder and making a much shorter design of turbine possible.

Messrs. Brown, Boveri, and Co. have also given their attention to the development of condensing plant. They now build for surface-condensing installations five different sizes of pumping sets, having on one and the same shaft the circulating, air, and condensed-water pumps, besides the impulse steam-turbine for driving the whole. Similar pumping sets are also built for electric-motor drive. Among their advantages are extreme simplicity and safety in running, and they occupy but a limited space, while allowing the very highest vacua to be reached. The firm also build turbo-compressors and blowers, which can be direct coupled to high-speed electric-motors or steam-turbines. The conditions under which these machines work often require a varying output, and this being obtained by speed variation, the steam-turbine is admirably suited for driving.

As is well known, Messrs. Brown, Boveri, and Co. were the pioneers in applying three-phase current to traction on railways, and the lines they have thus equipped are known as representative types, such, for example, as the Burgdorf-Thun line, built in 1899, the first of its kind, and the electrification, in 1905, of the Simplon Tunnel line. In this connection a passing reference may be given to other interesting lines which have been equipped by them, among which are the Seetalbahn, 5500 volts, single-phase; the Martigny-Orsières line, 8000 volts, single-phase; the Gergal-Santa Fé line, South Spain, 5500 volts, three-phase. They have in hand at the present time equipments for the Wiesenthalbahn, 15,000 volts, single-phase; for the Prussian State Railway, Dessau-Bitterfeld, a 600-horse-power goods locomotive, 15,000 volts, single-phase; for the French Southern Railway, 12,000-volt single-phase locomotives; for the Rhätische Bahnen, seven locomotives, 10,000 volts, single-phase.

Among their other specialities may be mentioned that they have designed a system of electric train-lighting apparatus which has been adopted, to the exclusion of all others, by the Swiss Federal Railways; 900 such apparatus have been supplied by them to the Paris-Orleans Railway Company, who have recently ordered 160 more. They also build heavy electric-motors for all kinds of current, and have supplied recently one of 2500 horse-power for rolling-mill driving at the Dudelingen Works, this being for three-phase alternating current; also direct-current winding motors for mines—viz., the Rastenberg, Volkenroda, La Mourière, Mauveschacht Mines, and others. Of late, the double-commutator motor, of the Déri type, has found favour as a winding motor, owing to its easy reversibility, and the range of power over which it is capable of regulation. Their single-phase commutator motors are finding extensive application for the direct driving of ring spinning-frames, cranes, &c.

The general arrangement of the Baden works is, as we have stated, shown by the plan, Fig. 1, above referred to, while a general view is given in Fig. 2, page 47. A good idea of the various shops and of the work they turn out is afforded by the views, Figs. 3 to 19, which we publish this week on Plates VI. to IX., and on the present page. Of these illustrations Fig. 4 shows a steam-turbine of 3000 horse-power running at 3000 revolutions, coupled direct to a three-phase generator of 2000-kw. capacity at 3150 volts and periodicity of 50. Fig. 5 illustrates a blast-furnace blower of a capacity of 32,000 to 25,000 cub. ft. of air per minute at a pressure of 11 lb., 18 lb., and 24 lb. per sq. in. This was built to be coupled direct to a Rateau turbine to develop from 2000 to 2800 horse-power. Fig. 6 shows a blower built for steel works, of a capacity of 5300 to 28,250 cub. ft. per minute at 35.6 lb. to 5.7 lb. per sq. in. This is shown coupled direct to a Brown-Boveri turbine of 3250 horse-power running at 2500 revolutions with steam at 128 lb. pressure, superheated to 250 deg. Cent. Fig. 7, Plate VII., is an illustration of a turbo-compressor set of 4060 cub. ft. per minute at 85 lb. pressure, driven by a Brown-Boveri exhaust-steam turbine of 740 horse-power at 3800 revolutions, for a French colliery company. Fig. 8 represents another turbo-compressor set of 2225 cub. ft. capacity, direct coupled to a 500 horse-power Brown-Boveri-Parsons turbine running at 4500 revolutions, using saturated steam at 7 kg. per square centimetre (99 lb. per square inch). direct to a 7000-horse-power water-turbine at a speed of 128.5 revolutions; the generator is a 3200-volt 45-period machine. Fig. 19, subjoined, represents the erecting-shop for large generators and motors, and shows a stator for a 17,000-kilovolt-ampere 10,500-volt, 50-period generator for a speed of 250 revolutions.

In close proximity to the offices is a large building, which covers the older part, if we may so style it, of the plant. In this are carried out a large number of mechanical operations, mostly in connection with electrical machinery. The building measures 170 m. (557 ft.) in length, and 60 m. (197 ft.) in width. It contains a large variety of lathes for all the detail parts entering into the

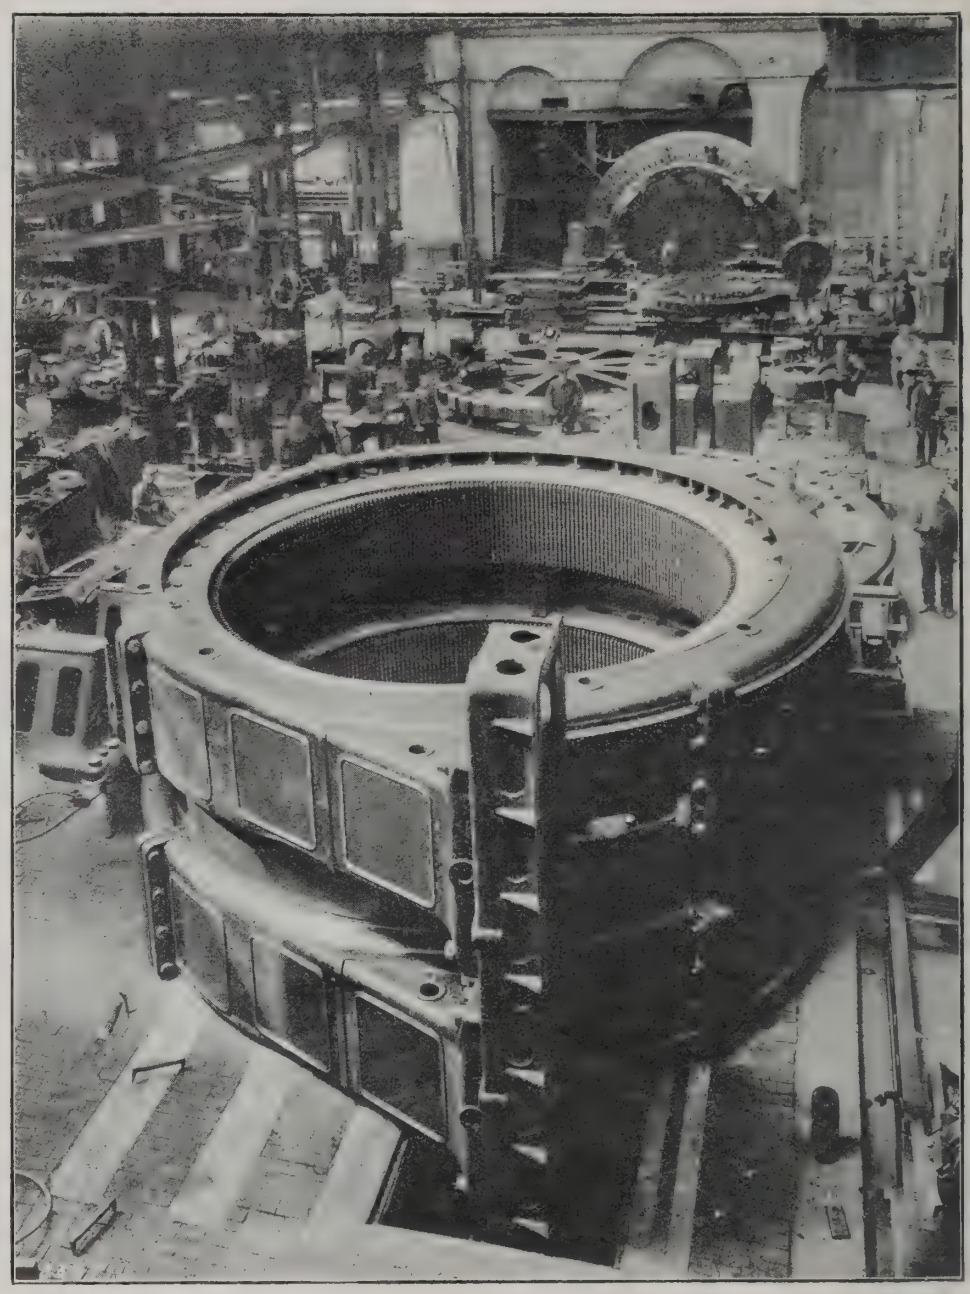

FIG. 19. ERECTING-SHOP FOR LARGE GENERATORS AND MOTORS.

Fig. 9 shows two blast-furnace blowers of 25,000 cub. ft. capacity per minute each. Fig 10 is a view in the compressor fitting and erecting shop. Fig. 11, Plate VIII., illustrates a 30,000-cub.-ft. blower direct coupled to a 450-volt continuous-current shunt-wound motor of 1100 horse-power at 1770 to 2000 revolutions. Fig. 12 illustrates condensing-pump sets in one of the testing-rooms. Fig. 13 is a view in the transformer, motor, and generator winding-room. Fig. 14 represents the winding-shop for slow and high-speed motors and generators. Fig. 15, Plate IX., illustrates the segments of a stator for a three-phase 4850-kw., 3200-volt, 45-period generator at 128.5 revolutions. Fig. 16 is a view in the erecting-shop for alternating and continuous-current motors. Fig. 17 shows the erecting-shop for double commutator motors. Fig. 18 illustrates a three-phase generator for coupling construction of electric dynamos and motors; automatic screw-cutting machines for screws and bolts; semi-automatic Gisholt lathes, which are mostly used for turning the covers, spiders, and other elements of electric motors, each piece being finished at one setting on the machine; other semi-automatic lathes for repetition work; a variety of grinding-machines for shafts, of milling machines, &c. All the smaller machine-tools are driven by belting from overhead shafts, the larger ones having separate electrical drives. The whole of the power used throughout the works is obtained from the hydro-electric stations above referred to, and two-phase current at 110 volts is employed, this also applying to the lighting. The western end of the building is occupied by lathes for turbine work and by an erecting-shop for low-speed generators, for commutators, and for single and three-phase motors.

On two sides of this same building are two

inspecting departments for the checking of the detail parts entering into the construction of electrical machinery and steam-turbines.

Close to one of the inspecting departments, and in an underground room, is a measuring-machine made by Messrs. Pratt and Whitney, placed here for the purpose of assuring a constant temperature. This machine enables errors in measurement down to a thousandth of a millimetre to be detected, and is of great service in enabling the engineers to maintain their gauges perfectly accurate. Close to this is a tensile testing-machine for ascertaining the strength, elastic limit, and elongation of iron, steel, and different alloys used throughout the works, also the strength of turbine-blades fitted in their groovings.

In the same building there are three large horizontal and vertical milling-machines for grooving the armatures for high-speed generators, and for cutting keyways in large shafts. Also gear-cutting machines for cutting gears on the revolving system up to a diameter of 2 m. (6 ft. 6 in.). There is also a high-speed milling-machine which has a feed of 550 mm. (21.5 in.) per minute, taking a cut of 10 mm. ($\frac{3}{8}$ in.) deep and 100 mm. ($3\frac{15}{16}$ in.) broad; and, in addition, a number of millers equipped for general work. The bays in this building, as in all the others throughout the works, are equipped with electric overhead travelling-cranes for loads ranging from 2 to 30 tons, as above stated, according to the work to be handled in each respective bay.

The turning-shop contains lathes of different makes, these being used for turning steam-turbine parts and those of electric generators. Among them are heavy lathes for machining large turbine-shafts. In Fig. 3, Plate VI., is shown one of the large lathes for turning turbine rotors. The low-speed generator erecting-shop, which adjoins the turning-shop in the western end of the building, contains an hydraulic press for pressing the armatures and bearing-ends on the shafts.

In a line with this building is the pattern-shop, having two floors, the larger patterns being manufactured on the ground floor. This shop is equipped with modern machinery, exhausters for removing the dust, chips, &c., being fitted to each machine. Adjoining the pattern-shop are the iron and brass foundries, as shown in the plan, Fig. 1. Both foundries contain a number of moulding-machines for moulding in series small cast-iron and brass pieces.

The steam-turbine fitting and erecting department is parallel with the machining building. It is 95 m. (312 ft.) in length and 60 m. (197 ft.) in width, and is divided into eight bays. The first bay on the east side is set apart for general grinding work, and forms also a repair shop for carrying on the general repairs to machinery throughout the works. On the floor above this is the tool-making department, thoroughly equipped for the manufacture of all kinds of tools, jigs, and gauges used in all the machine-shops, including cutters, reamers, spiral drills, taps, &c., all being hardened and ground. Each shop throughout the works has its own tool-room, which is kept regularly supplied with tools for repeat work from a tool-store, in which all the tools are admirably classified. In fact, the cutting-tools and gauges manufactured by Messrs. Brown, Boveri, and Co. for their own use are most excellent specimens, which compare favourably in every respect with those of other firms who have made tool manufacture their speciality.

In the next bay of the steam-turbine fitting and erecting department is the erecting-shop for high-speed electric generators for coupling to turbines. Then follows the erecting-shop for turbines, blowers, and compressors, and condensing machinery; and the boring-mill shop, which has a series of horizontal boring-machines for boring cylinders up to 4 m. (13 ft.) in diameter and 7 m. (23 ft.) in length. The remaining bays are set apart for the erecting of all turbine work.

At the western end of this same building, and close to the boiler-room, are two steam-turbines which act as a stand-by to supply current throughout the works for power and lighting, should an accident occur to the hydro-electric current-generating stations above mentioned. These turbines are coupled to two-phase generators. In the same bay is another very interesting feature of the works —viz., the highly developed turbo-generator testing department. This consists of a battery of five boilers for the generation of steam up to the highest temperatures for testing purposes, and a duplicate condensing system connected up to the ten beds on which sets can be simultaneously or independently tested. All turbo-generators are tested before leaving the works.

Alongside the boiler-house is the coppersmiths' and pipe-shop, and in close proximity are the sheet dépôt and the stamping-shop for the manufacture of stampings for dynamo armatures.

The winding-shop for the manufacture of field-coils for machines of all sizes and powers is a separate building, measuring 50 m. (197 ft.) square. It also contains the transformer department and a testing-room. This winding department forms one of the most interesting features of the works, as it is admirably equipped in all respects. It includes the manufacture of transformers, and contains a complete installation for drying the transformers; in this the complete transformer, up to the largest size and for the highest tension, is placed in a vacuum stove filled with its oil, and in this way all moisture is removed. In an upper storey of the same building is the winding section for small motors, &c., where female labour is mostly employed.

Various other shops and stores are distributed at convenient positions throughout the works, as shown in the plan (Fig. 1). The smithy, a clean, carefully-lighted and ventilated shop, is at the north end of the works. It measures 50 m. (164 ft.) in length and 25 m. (82 ft.) in width, and contains three steam-hammers served by open fires, and two re-heating furnaces. Messrs. Brown, Boveri, and Co. purchase their large forgings and about two-thirds of their castings from outside sources. Close to the smithy is a two-storey building, containing a large variety of most ingenious machines for braiding wires; further south being the fitting-shop for castings, containing sand-blast machines; and to the extreme southern end the fitting and erecting-shop for switchboards and for the railway-lighting apparatus.

A canteen has been provided by the firm. This is managed by a club formed by the men who choose to take their mid-day meal at the works. They appoint their own committee, who deal with all matters connected with the canteen, and all profits made are set apart for reducing the cost of the food and drink supplied.

The men are paid at daily rates and by piece-work, wages being paid to the workmen fortnightly. They live at Baden and in the neighbouring townships and villages, where Messrs. Brown, Boveri, and Co. have provided for them dwelling facilities. Further developments in this respect are under contemplation. The men, together with the other employés, are insured against accident by the firm, and have their own sick-fund.

THE JUBILEE MEETING OF THE INSTITUTION OF NAVAL ARCHITECTS.

(*Concluded from page* 28.)

THE Jubilee meeting of the Institution of Naval Architects, of which the proceedings up to the 5th inst. were dealt with in our last issue, were continued on Thursday, the 6th inst., when technical papers were read at meetings in the buildings of the Institution of Civil Engineers and of the Institution of Mechanical Engineers. In both cases the proceedings opened at 11 A.M.

THE DEVELOPMENT OF SHIPBUILDING IN JAPAN.

The meeting at the Institution of Civil Engineers was presided over by Lord Brassey, and the first paper taken was that on "The Development of Merchant Shipbuilding in Japan," by Dr. S. Terano and Mr. M. Yukawa. In the absence of the authors this paper, which we hope to reprint in a later issue, was read by Dr. K. Suyehiro, of the Department of Naval Education, of Japan.

The discussion was opened by Professor F. P. Purvis, of Tokio University, who said that the paper gave an excellent summary of the development of Japanese Shipbuilding. He noted that in one place it was mentioned that there were now 230 private yards in Japan, but that the majority were of very small size. He would like to point out, however, that many of these yards were capable of building ships of up to 1000 tons, and that with very small appliances they produced very good results. In general, the yards experienced no difficulty in getting Japanese-built engines for the steamers they constructed, but the supply of boilers was more restricted, and some of the yards had consequently put down boiler-manufacturing plant of their own. He recommended anyone interested in the progress of Japanese shipbuilding to pay a visit to one of the six recent steamers of the Nippon Yusen Kaisha, during their visits to the Port of London. It would, indeed, be a good idea to take a trip to Antwerp in one of them.

Dr. S. J. P. Thearle, referring to Professor Purvis's suggestion that one should pay a visit to one of the Nippon Yusen Kaisha's Japanese-built steamers, said that he had had an excellent opportunity of seeing one of these boats, as he had been to the Coronation Review on board of her. He had been much impressed with the excellence of the workmanship, and would particularly like to mention the teak deck, which was the most magnificent piece of work of its class which he had ever seen. Referring to the Act, of 1896, for the encouragement of shipbuilding, he would like to say that in 1897 certain ships were built in England for Japan under his personal supervision, and one of the conditions of the contract was that complete drawings and models should be supplied to the owners in such detail as to enable later similar ships to be built in Japan. Arrangements of this class had been of great assistance to Japan in building up her industry. Although the greater part of the shipbuilding material was now supplied from abroad, Japan had plenty of natural resources, and no doubt in the future she would produce much of it herself.

Mr. A. Isakson, President of the Swedish Institution of Naval Architects, said that he had recently been in Japan, and that the paper had been of great interest to him. On the question of the importation of foreign material into that country, he would like to mention that while at Kobe he saw a floating-dock under construction, the whole of the material for which was of Japanese manufacture. There was little doubt that the Japanese steel works would greatly develop in the future. He had been much impressed by the Mitsu-Bishi Dockyard, which he considered one of the most wonderful in the world. Those who had not visited it could hardly have any idea of its extent and completeness. He had also been very much struck by the physique of the workmen, and as they received only from 1 to $1\frac{1}{2}$ yen a day, he could hardly understand why shipbuilding could not be carried out more cheaply in Japan than in Europe, even allowing for the greater cost of material.

Sir William White said that he had had some experience in connection with the advances made by Japan, and would point out that the policy carried out by her, of making it a condition of contract that a certain number of Japanese students should be received into the works carrying out a contract, and associated closely with it, had greatly assisted towards the wonderful developments that had taken place. None the less, the progress was astonishing, and represented the creation of the Japanese marine in about 16 years. The rate at which the shipbuilding industry had progressed possibly had something to do with the fact that costs were still high, although labour charges were low. It was probable that the whole organisation was still so new that the various interests concerned had not yet shaken down to a proper balance. Ultimately, it was quite possible that Japan might become a serious shipbuilding competitor of Europe. He was tempted to say something about the question of subsidies. Adam Smith had laid it down that direct encouragement of this sort might be useful in the early days of industries, but held that a period would come later at which the encouragement was undesirable. He noted that the original Act for the encouragement of shipbuilding had been drawn up to cover a period of 15 years, but that as soon as it ran out it had at once been extended for a further period of 10 years. His impression of the history of subsidies in general was that once started they were very difficult to stop. It was probable, however, that the Japanese shipbuilders had no wish to see them stopped.

The Chairman associated himself with all that had been said about the wonderful skill and industry exhibited by Japan in creating her shipbuilding trade in such a short space of time. None the less, he thought that we as a nation could not altogether regret that for some time yet Japan would look to us for assistance towards the still greater developments which she would without doubt make.

Dr. K. Suyehiro then briefly thanked the meeting for its attention to the paper, and stated

the regret of the authors at their inability to be present.

Fifty Years' Development in Mercantile Ship Construction.

The reading of the second paper was then proceeded with. This, by Dr. S. J. P. Thearle, Chief Ship Surveyor to Lloyd's Register, dealt with "Fifty Years' Developments in Mercantile Ship Construction," and we reprint it on page 69. It was read by its author.

Mr. J. Foster King opened the discussion. He thought that Dr. Thearle's paper gave a very wide and interesting review of the history of mercantile shipbuilding, and that within the limits allowable it would have been impossible to go into more detail than he had done. There was, however, one small point he would like to raise; that was, the remarkable simplicity of construction which was employed now as compared with the practice of twenty-five years ago. The features necessary to stiffen a ship had practically been removed from the inside to the outside. This was a development for which the shipowner should be particularly grateful. In reference to modern double-bottom constructions, he would say that they had several times been put to the best possible test—that was, the test of bad usage—and had shown themselves most satisfactory. He had had one very bad case of grounding, and although the plating was seriously perforated, there was no damage to floors or tunnel construction

Dr. G. B. Hunter said that he would like to echo the remarks of the paper in reference to the Great Eastern. She was a most remarkable and able specimen of shipbuilding. In reference to the question of the improvement in shipbuilding practice of recent years, he wished to express the appreciation of shipbuilders in general for the sympathetic attitude exhibited by the Committee of Lloyd's Register, and by Dr. Thearle personally, towards their efforts in the direction of improvement. There was a point in reference to the first use of cellular double bottoms he would like to raise. Unless he was mistaken, his firm had introduced the longitudinal frame system in a boat built in 1876. This was an earlier date than that given in the paper.

Mr. Stevenson Taylor, President of the Society of Naval Architects and Marine Engineers of the United States, who was called upon by the Chairman, said that he was rather surprised at being asked to speak on the paper just read. He had rather expected to reserve his remarks for the later one, which dealt with shipping on the Great Lakes. With the permission of the meeting he would deal with the two together. He was very glad to have Dr. Thearle's contribution, and it would be particularly useful for future reference. In the matter of the developments on the Great Lakes he would point out that there America had a field in which she was free from the competition of England or Germany, or any other country. The existence of the lakes was really responsible for the development of the industries, the materials for which were transported over them. The wonderful developments there had shown what his country could do in the shipbuilding industry, and it was his belief that his people would not be prepared permanently to allow the whole of their carrying trade to be dealt with in ships built even by such leading maritime countries as England, Germany, and Japan.

Mr. T. Utley said that he thought there was one point on which finality in ship design was far from being reached. This had reference to the question of the lighting and ventilation of passenger ships. Some few years ago a side light 16 in. in diameter was the largest that it was possible to fit into a ship's structure, and even on the Olympic the largest size was only 24 in. by 19 in. The question of the size of lights in passenger steamers was of very great importance, and he thought that Lloyd's and the Board of Trade should modify their rules in reference to frame spacings in order to allow better arrangements than were now possible to be fitted.

The Chairman, in closing the discussion, said that he always took great interest in anything that was said about the Great Eastern, as his father had been the largest shareholder in her. He thought her commercial failure was due to the fact that she had no superiority in speed over her rivals. As one interested in sailing-ships, he could not help feeling some regret at their gradual supersession by steamers. Forty-nine years ago he had, when anchored off Cape St. Vincent, seen some forty sailing-ships lying in shelter at the same time. In the same waters to-day one could see nothing but steamers, and yet the winds were still blowing across the seas as they had ever done. It seemed a pity that they should not be utilised, and he suggested that the apparent coming of the internal-combustion engine might possibly lead to a revival of the system of using auxiliary power on sailing-vessels.

Ore Transportation in America and Sweden.

At this stage Lord Brassey retired from the chair in favour of Sir William White, and Professor Sadler read the paper on "Shipping on the Great Lakes," by Mr. Frank E. Kirby and Mr. A. P. Rankin; while Mr. J. Johnson read his paper on "Recent Developments in the Sea Transportation of Swedish Ore." There was no discussion on either of these papers, which are reprinted on pages 57 and 62 of this issue.

The paper dealing with the "Design and Service Performance of the Trans-Pacific liners Tenyo Maru and Chiyo Maru," by Dr. S. Terano and Professor Baron C. Shiba, was taken as read, and there was no discussion on it. We hope to reprint this paper later.

The proceedings of this section thus terminated for the day.

Naval Engineering in Japan.

The meeting held in the hall of the Institution of Mechanical Engineers on the morning of the 6th inst. was presided over by Admiral Sir Gerard H. Noel, and began at 11 A.M. The first paper to be taken was one by Engineer-Rear-Admiral Terugoro Fujii, Engineer-in-Chief of the Japanese Navy, and was entitled "Progress of Naval Engineering in Japan." This paper, which we hope to reprint in an early issue, gave an account of the development of steam machinery in the Japanese navy, the introduction of which commenced in 1863, with the gunboat Chiyoda Gata. The paper gave descriptions and brief particulars of the Miyabara and "navy-type" water-tube boilers, now largely used in Japanese warships, alluded to the adoption of turbines, and gave the results of trials of Japanese-built turbines. Particulars of the *personnel* were also given, with a few particulars as to the cost of machinery, the latter being summarised by the author in the words that, "generally speaking, the cost of propelling machinery in Japan seems slightly less than it is in Europe and America. This is probably due to the lower wages of workmen, notwithstanding the higher price of imported materials." Although wages are rising rapidly, the average pay of workmen is about 1s. 4d. per day of about 10 hours. The author concluded with some remarks upon the effect of war upon machinery, stating that during the whole course of the recent war the machinery developed no "defects such as to affect the action of the fleet," although in some cases warships were continuously under steam for over 2000 hours. "The only noticeable trouble which our engineers experienced was the leakage of both main and auxiliary condenser tubes. Also," continues the author, "I may add that the spare parts of auxiliary machinery were found indispensable, they having been used very often." With torpedo-boats and destroyers no serious troubles were experienced.

In the absence of the author, the paper was read by Engineer-Commander Keijiro Matsui.

The first speaker on the subject of this paper was Mr. A. E. Seaton, who thought the invitation extended to him to speak first not altogether inappropriate, for no less than thirty years ago he had been asked to take certain pupils, and on his consenting, two Japanese gentlemen had come to him for instruction. One of these was a now well-known Japanese Admiral. He came to him well-educated for that time, as education went in Japan, but knowing very little English, and he had helped him in that subject of necessity. The demand for knowledge, for the reasons and factors influencing design, on the part of these and other Japanese students who came to him, had resulted in the production of his book. He had had the honour of designing the machinery of what might be termed the first modern warship of Japan. At a time also when the British boats of the "Gem" class could only maintain, by dint of very hard work, a speed of 12½ knots, the Japanese, wanting something better, had adopted his advice and fitted boilers which gave 14 knots. The real point of the paper was brought out towards its conclusion and was concerned with the effect of war upon ships' machinery. The picture there given was a very gratifying one. The Japanese were a people who would not be betrayed into buying cheap things. They insisted on the best, and the result under war conditions was as shown in the paper. As a people, he thought that they purchased with economy; they could get as much out of a sovereign as anybody. The paper dealt with only naval matters, but, of course, the merchant marine had shown equally great development, both for passenger, tramp, and other services. He thought the people gained much by approaching subjects without prejudice, or engineering and other bias. If one could divest oneself of preconceived ideas, or the influence of the opinion of the "man in the street," it would be much the better.

Admiral H. J. Cone, Engineer-in-Chief of the United States Navy, said he had been much impressed with the class of merchant ship now flying the Japanese flag and plying between the United States and Japan. The vessels he had inspected were particularly well equipped throughout. They were taking traffic away from the United States and European countries.

Captain Tuxen said he belonged to a small navy, but one of old and proud traditions (Denmark). Their experience had been that it was very difficult to improve in the right way without making some mistakes. The Japanese had made immense progress, which had not been offset by any failures, and he thought they must congratulate the Japanese, therefore, on the cleverness of their engineers.

Mr. J. M. Allen said his firm had done much work for the Japanese, and he was interested, therefore, to hear that their Miyabara boiler had given such satisfaction.

After a brief acknowledgment by Commander Matsui, on behalf of the author, of the remarks passed on this paper, the Chairman said that he had had the privilege of seeing something of the Japanese, as he had been on the China Station during and after the war. On visiting Japan after the war he was shown over the dockyards at Yokosuka, Kure, and Sasebo, and could not help noticing that a state of great activity was still being maintained. Their works and methods showed them to be progressive. Everything was up to date.

Training of Naval Architects.

The next paper was one by Professor Flamm, entitled the "Scientific Study of Naval Architecture in Germany." This paper we print on another page of this issue. It was concerned primarily with an account of the methods of education followed at the Königliche Technische Hochschule zu Berlin in Charlottenburg. Professor Flamm explained that he had hoped to show by means of cinematograph films what class of work was kept before the attention of students. The films were photographs of propellers, showing cavitation effects, &c., taken at Charlottenburg. Owing to the strong daylight in the hall it was impossible to exhibit these at the Thursday meeting, and their display was therefore postponed until Friday morning at 10.30, special arrangements for darkening the hall having meantime been made. With these cinematograph views, and the discussion to which they gave rise, we refer in due order in a later part of this report, under the heading "Propeller Phenomena."

The discussion on Professor Flamm's paper was opened by Sir William White, who thought the Institution indebted to the author for the detailed account of the course of training at Charlottenburg. He had made a study of technical education in most parts of the world, and had gone, among other places, to Charlottenburg. The methods adopted there were not all of them applicable here. There were, for instance, here no leaving certificates given by the secondary schools. The German system provided such certificates, which were presented to the university by intending students, and were accepted as proof of sufficient ability. He had known cases, as a result of this difference, of Englishmen wishing to study at Charlottenburg experiencing difficulty in convincing the authorities of their fitness to take up the work. Then, again, the German system involved a four-years' course, the English one of three years. There was more breadth and greater freedom in the German course as far as the first examination. Here we had no great critical intermediate examination, as in Germany. The work here was progressive and cumulative up to the final examination, with account taken of the work done by the students during the sessions. This he thought the more satisfactory

arrangement, as it was an undoubted fact that many students capable of excellent work could not acquit themselves satisfactorily at examinations. This system involved the use of internal examiners familiar with the work of the students and college course, but these must be coupled in some measure with examinations held under external examiners in order to keep the standard to the necessary level. The German system was distinguished for the minute subdivision of the subjects taught. Subjects were not separated to the same extent here. Perhaps separation went too far in Germany and not far enough here. The ideal lay somewhere between the two. These remarks applied to the relation of naval architecture and marine engineering. He was a naval architect, but he had received instruction in marine engineering. Mr. Seaton was a marine engineer and had received instruction in naval architecture, and, he thought, in both cases to their mutual advantage. The course of the French Genie Maritime combined both. Whatever methods, however, were adopted in the German system, with their reputation for thoroughness or organisation, and working on the knowledge of what had already been done elsewhere, it might be taken for granted that the Germans had taken their steps deliberately, and they were, therefore, well worth the study of others.

Professor C. H. Peabody, one of the delegates from the United States, spoke next; he said he wished to emphasise the points made by Sir W. White. When he had been to Charlottenburg he had been impressed with the great similarity of the work done there to that done at the colleges in the United States, though he had expected to find it very different. The United States schools formerly followed the tutorial system, but had since changed to the lecture system. Professor Flamm had laid great stress upon the tutorial system, which they had partly abandoned. This tendency in Germany was interesting. He strongly dissented from the suggestion that a youth should have some workshop experience preliminary to college work. His experience showed that such a course was not attended by good results on the whole, though it was sometimes advantageous. He hoped that no steps would be taken in the direction of making this compulsory. It was bad to break off the work of the school. It added to the age at which the student came to college. It was extremely unfortunate that in Germany the age was of necessity as high as twenty-one. The age of nineteen was too high—higher, at any rate, than it ought to be—for the average youth to come to college. He had found that youths coming to him at the age of seventeen had done themselves the greatest credit. It was desirable that they should get early to their real work.

Sir W. White here interposed a remark on the subject of training, stating that the Institution of Civil Engineers' conference of last week had shown, he thought, that the bulk of opinion was against Professor Peabody's view, and favoured some preliminary practical work, and that in Germany, where they had had twelve years' experience of the interposition of one year's practical work before college, the tendency was rather to lengthen that period than to shorten it.

Professor Hovgaard followed, remarking on the clearness of the statement placed before them. The system was well adapted to the desired end, and had been evolved with much forethought. He thought practical training necessary at some stage or other, but was not prepared to say at what stage; it must be procured, however, at some period. The advantages derived from it were both direct and indirect. Men became familiar with tools and methods, but they also came into contact with the workmen, and so came to see things from a point of view that it was impossible to attain later. With regard to the so-called tutorial method as he understood it, the aim of the system was to make the lectures work hand in hand with the practical work and design. The course he advised for naval constructors followed this system, the lectures being followed by the application of information so conveyed to the practical work of design.

Professor Marbec, of the École du Genie Maritime, said the teaching of the two professions of marine engineering and naval construction formed parts of one whole in France. The course of education was the same for both, and members passed from one division to the other. If there appeared to be special aptitude for one side, a special course was made to suit the circumstances. When their naval constructors finished their course they could take charge of work in either of the two branches. They had practically two periods, the first being given up to marine engineering, and the other to ship design. Each was preceded by a short course of the other, so as to bring out the bearing of one upon the other. The fusion of the two branches so far as the courses of education went in France was absolute.

Mr. S. W. Barnaby understood that Professor Peabody's point referred to the time at which practical training was necessary. There was still much dispute on the point, and he was of Professor Peabody's mind. The boys were better for going straight on with their theoretical training, and it should not be broken into by practical work.

Mr. A. E. Seaton considered it most important that the young men should have their ideas turned into practical directions. There was much to be learnt in connection with launches, the lifting and handling of heavy weights, and a vast number of other practical matters which could not be taught in the shops.

Mr. A. J. Maclean, of New York, referred to Sir W. White's remarks on training, and said that though that gentleman had studied the question of technical education in all parts of the world, there was certainly one institution he had not visited, that was the Webb Naval Academy, of New York. In his young days the founder, Mr. Webb, had experienced great difficulty in securing information he needed, and had formed the resolution that, fortune favouring him, he would found an institution at which such instruction would be procurable. In due course Mr. Webb was able to give concrete form to his wish. The college had now existed for seventeen years, and for fifteen of these he (Mr. Maclean) had held the chair. They took lads of from fifteen to twenty; they much preferred young men. The syllabus closely resembled that given in Professor Flamm's paper. Practical work was followed in the course, including, for instance, lining off in a moulding-loft. They went thoroughly into all the calculations regarding both ships and machinery. Their lads were readily taken up on the completion of their courses; they refused government posts, as they were easily able to get better positions and salaries. Arrangements were made for them to get sea training, and this was chosen for them according to their decision on graduating.

Dr. A. Denny said he started at 16 with three years in the works, accompanied by evening classes, this being followed by the course at the Royal Naval College at Greenwich. In Germany the students were 21 before they began their courses. He admitted that his training preliminary to the college had been somewhat imperfect, but it was otherwise with regard to the Admiralty men, who were well prepared for it. If the German course carried mathematics, for instance, higher than did that at the Royal Naval College, he thought it must go very high indeed. His son started in the same way and had been trained under Professor Peabody. One of the solutions was the sandwich system, which was possible on the six months' plan in Scotland. In this way they could get four courses into three years. He thought it would be found, however, that all methods had been known to give good results. He wished to ask what became of the vast number of young men turned out by the colleges. Did they ultimately obtain employment? The production in the United States and in Germany, he was afraid, out-ran the demand. Here that stage had not yet been reached. He thought the training question capable of summary by the statement that any system properly carried out would produce good results.

Mr. E. A. Sperry, one of the delegates from the United States, thought it would generally be found that young men got positions in proportion to their capabilities, with stress on the "capabilities."

Mr. J. M. Allen followed with the remark that in his experience the sandwich system had proved unsatisfactory. College men had airs, and there was often trouble between them and the foreman. He thought three years' works first was best. His firm were in the habit of granting facilities for college instruction after three years' works experience.

Professor Flamm, in replying to the discussion, said that at Charlottenburg they had men from all over the world, and had found many of them first-rate students. It was, of course, impossible to grant them facilities greater than those accorded to their own men. Equality was necessary, and some line had to be fixed. The age at which the course finished was rather great, but they did not like to give the technical man a lower standing than the men of other professions. They therefore granted equivalent degrees, and this rendered similar schooling necessary. They had abandoned the dual system, and had thought specialisation better, because one man was incapable of acquiring complete knowledge in both. They also believed in allowing the men sufficient free time to enable them to gain some knowledge of the world and general matters. Too constant application to a limited subject was inadvisable. In the summer holidays the men went to sea or to works and earned money, spent subsequently while at their studies. With regard to the quantity of students, efforts had been made to keep the supply within the requirements, but the men were well fitted for other work, such as that encountered in connection with land work. He was pleased to say that, whatever their actual course of study, the best books of the world, among which were many by English authors, formed the foundation of their knowledge.

The Chairman thought that Germany was looked upon in the eyes of the world as an organised nation. One result of that organisation which had been mentioned in the paper appealed to him. It was the military service required of young men. He would like to see it here for physical reasons. One year of military training would greatly improve our students.

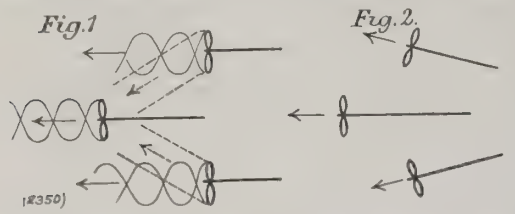
Cavitation.

The next paper taken was entitled "Some Further Notes on Cavitation," and was by Mr. Sydney W. Barnaby. This was read by the author, and is reprinted on page 55 of the present issue.

Dr. A. Denny said he did not agree with Mr. Barnaby's theory. Thrust as high as 16 lb. per square inch was not uncommon in their experience, with good results. He knew of one case where it was as high as 22 lb. With regard to the use of the term "efficiency," now that tanks were common he thought some standard meaning should be adopted for terms used. Efficiency should include the hull effect. It should be brake horse-power compared with indicated. Spectacle-frames, brackets, &c., form some of the penalties of the use of twin screws, and should be included in the expression for efficiency. In their tank the actual thrust was measured, and the turning moment could be measured separately for one, two, three, or four screws. They drove the screws until a point was obtained at which the resistance and propulsion curves crossed. They found the subject to be one in which the further they went the further they wanted to go. Some day he hoped to place their results before the Institution. It was because there were so many problems involved that he wished the Bushey tank to be reserved for scientific work. The results obtained in their own tank were accurate to a practical degree. Referring to a portion of Professor Flamm's paper, he would say that sea-water was not homogeneous. It contained air, which was liberated under the action of the propeller. He would like to know the limiting velocity of the water when this action occurred.

Professor Flamm spoke next, regretting that it had been impossible for him to exhibit photographs in connection with his paper, as they proved, he considered, that the greatest effect was given by the suction rather than by the thrust. The surface of the water was drawn down and a hollow formed on the surface above the revolving screw. If there were thrust present, the surface would be raised rather than lowered. Also it was found that air was sucked in in front of the propeller. Where there was cavitation he found the thrust to be greatest; but if air came down to the screw, the thrust was destroyed. In shallow-draught boats, therefore, it was advisable to prevent the inflow of air by means of a flat board or surface over the screw. When a vessel was passing through waves the depth of water over the propeller was sometimes so reduced that the thrust was destroyed, and this might be one of the reasons why ships with heavily-loaded propellers lost so much speed in bad weather. The spiral developed in the water when cavitation occurred was cylindrical and parallel, as shown by his photographs. He had carried out some experiments in connection with the propulsion of the Siemens Schuckert airship, which were of

some interest. This airship had sets of three propellers, as in the accompanying diagram, Fig. 1. It was found that if the two outside propellers were set to work, a sharply-defined cylindrical horizontal column of air was set in motion behind and in line with the axis of each propeller. The third propeller was between and somewhat behind the other two, and when that also was set in motion it was found



that the streams from the two other propellers were drawn in towards the third, as shown by the dotted lines. Each propeller singly developed parallel flow or column of moving air. The expedient had therefore been adopted of setting the forward screws at an angle, so that their streams should not flow into the third, as in diagram Fig. 2.

Mr. A. E. Seaton said no tanks were available in his day, and he had had to use an ordinary dinghy for the purpose. Hanging over the counter he had made observations which had been good enough to be serviceable, and many of the things now known were capable of examination in this manner.

At the close of the discussion, Mr. Barnaby asked Dr. Denny if he would mind stating the conditions under which a propeller with 22-lb. thrust had been used, to which Dr. Denny replied that it was a steamer in channel service.

Collapsing of Beams and Elastic Curve Strips.

The last paper for consideration was one by Professor Marbec, entitled "Notes on the Collapsing of Beams and Elastic Curve Strips." This was read in abstract for the author by Lieutenant Boris. There was no discussion on it, and the meeting immediately afterwards adjourned.

Luncheon at Lloyd's.

At the conclusion of the reading and discussion of papers on Thursday, the 6th inst., many of the members lunched at Lloyd's Register of Shipping in Fenchurch-street. After the loyal toasts that of "The Institution of Naval Architects" was drunk, and replied to by Dr. Archibald Denny; it was followed by that of "Delegates from Foreign Countries," coupled with the names of Mr. Stevenson Taylor and M. Bertin. Lord Furness proposed the toast of "Lloyd's Register and its President, Mr. Thomas L. Devitt." The latter referred to the eleven scholarships in naval architecture and marine engineering maintained by the Register. Speaking of the Society's new rules for the construction of steel vessels, Mr. Devitt said that since they came into operation in July, 1909, plans had been dealt with for the marvellous total of 1555 vessels, of 3,278,000 tons. The total tonnage now under construction in the United Kingdom — viz., 1,476,394—was the largest on record. The tonnage actually under construction at the present time at home and abroad to class at Lloyd's Register was 1,237,600 tons, and this was the highest figure on record with the exception of the period March, 1901, to March, 1902. Of the sea-going vessels under construction abroad no less than 57½ per cent. were to be classed with Lloyd's.

Reception at the United States Embassy.

In the afternoon the members of the Congress and their lady friends were received at Dorchester House, the Embassy of the United States, by the Hon. Mr. and Mrs. Whitelaw Reid. The reception was largely attended, and after the treasures of the magnificent mansion had been inspected, tea was served in the garden.

The Jubilee Banquet of the Institution.

The Jubilee Banquet was held in the Grand Hall of the Connaught Rooms, which was charmingly decorated in appropriate designs. There was a very large attendance of ladies and gentlemen. After dinner, the President, the Marquis of Bristol, stated that he had received a telegram from King George V., in reply to the loyal greeting sent from the inaugural meeting of the congress (see page 13 *ante*). The telegram was as follows:—

I am commanded by the King to thank the members of the Institution of Naval Architects for their expression of loyalty. His Majesty hopes the congress may be attended with every success.

The following telegram had also been received by the Duke of Connaught from the German Emperor:—

Please forward my sincerest and warmest congratulations to the members of the Institution of Naval Architects on the occasion of the jubilee meetings now held in London. May the Institution, of which I have had the honour of being an honorary member for sixteen years, always remain what it has been—a powerful promoter of naval building and engineering—and serve to unite in friendly intercourse the prominent men of all countries who devote their time to the noble task of shipbuilding and engineering.

After the loyal toasts, the Right Hon. Walter Runciman, M.P., President of the Board of Education, proposed the toast of "Our Guests," which was replied to by Vice-Admiral de Montferrand, President of the Armaments Commission of the French Navy, Geheimer Oberbaurat Hüllman, Director of Naval Construction of the German Navy, Rear-Admiral W. L. Capps, Chief Constructor of the United States Navy, and Major-General E. Feratti, of the Italian Navy. Sir William White next gave "Kindred Societies," and replies were made by Rear-Admiral Matsuo, of the Japanese Society, Mr. A. Isakson, of the Swedish Institution, and Signor Salvatore Orlando, of the Italian Society. The toast of "The Institution of Naval Architects," proposed by Rear-Admiral G. Dyrssen, President of the Swedish Admiralty Board, and replied to by the Marquis of Bristol, concluded the proceedings.

Propeller Phenomena.

An additional meeting was held at the Institution of Mechanical Engineers on the morning of Friday, the 7th inst., at 10.30 A.M., Engineer-Vice-Admiral Sir J. Durston being in the chair, in order to enable Professor Flamm to show his lantern-slides and cinematograph views illustrating screw-propeller investigations carried out at Charlottenburg. Professor Flamm explained that in their tank they had a working screw depending from a carriage running above the tank. The movement of the carriage was dependent on the pitch and speed of the screw, but they had also an attachment by which they could load the carriage in order to represent ship resistance, &c. This consisted of a weight suspended by a line passed over a pulley and attached to the carriage. The arrangement included a balance, so that alteration in the load could be noted. The views were taken with an exposure of $\frac{1}{1000}$ second, and showed excellently the physical effects attendant upon the working of the screw at different speeds. The screw, of course, moved through the water and drove the carriage. Arc lamps provided means of illumination through the glass sides of the tank.

Professor Flamm's views were in two series, both connected with the same subject. One film on the cinematograph was in illustration of what happened when a stream of water impinged on a curved hinged plate. The plate was suspended at one side on an axis parallel to the axis of curvature, and it was shown that when a jet of water was directed on to the convex side from the end nearest the axis, the plate rose to meet the jet instead of being thrust out of the way. This suction effect, Professor Flamm contends, exists in the case of the curved surface of a propeller. Some slides and the other films illustrated the suction effect on the water surface and the entraining of air, and the development of the cavitation spirals. Several of the lantern-slides have already been reproduced in ENGINEERING,* and need not therefore be repeated. It will suffice to state that they formed excellent illustrations of the effects to which Professor Flamm wished to draw attention, as did also the cinematograph views. The latter were particularly fascinating, the appearance and disappearance of the various phenomena being easily followed, as the representation of the screw and carriage passed across the sheet. The confusion resulting behind a propeller drawing air was extremely well seen, as was also the formation of the air-pipe down to the front of the propeller from the surface. The cavitation spiral and the central worm were also very distinctly seen. Professor Flamm explained the conditions of speed under which the screws were working, and also mentioned that, when air was sucked down to the propeller, the balance apparatus showed that the thrust was altogether destroyed.

Sir John I. Thornycroft, who re-opened the discussion on the paper, which had been read at the meeting on the previous day, said Professor Flamm had gone to a great amount of trouble to make the effects apparent which otherwise could not be easily recorded. He was sorry so much attention seemed to have been directed to the suction of air, for most engineers had been familiar with this for some time. He would like to see experiments carried out far enough below the surface to prevent air getting down to the screw. A flat surface arranged over the water where the tendency is greatest for air to be drawn down greatly increased the power developed by screws. Builders recognised that at the present day, and flat sterns were provided to prevent this suction with lightly-immersed screws. In connection with Professor Flamm's other demonstration—of the inability of a stream to detach itself from a curved surface—his own experiments with curved stern lines confirmed this, as did also that of the late Mr. Froude and the work with the Ramus model.

Mr. A. Isakson, Sweden, remarked that probably many had watched screws immersed to depths of 5 ft. or 6 ft. down in the clear water in some seas. He had recently watched them in the Indian Ocean, and had observed at the tip of each blade a bright air-bubble. He thought a means might be found of examining the partial vacuum effect at these points by boring holes through the propeller to the boss and shaft and putting them in communication with suitable gauges. The method, he thought, was quite feasible and might lead to interesting and valuable information.

Dr. A. Denny remarked that Professor, Flamm had conclusively proved by his photographs that the column of water leaving the screw was parallel and that no water was thrown outwards. There was no such centrifugal action, and he hoped that would prove the deathblow to the ideas of all inventors whose freaks were intended to counteract this action which did not exist. He had made observations of cavitation at sea on the King Edward. When that vessel had been run astern the screws did not suck air down, but there was cavitation, and spirals came off. In reference to his remarks of the previous day, he wished to observe, in order to dispel possible misapprehension, that only three or four of their apprentices were allowed to take their practical training on the sandwich system, and these were selected men. They could not do it for all.

At the conclusion of the discussion, Professor Flamm stated that he hoped, with financial assistance from the Government, to continue his experiments to include the action of two and three screws, and also the influence of a rudder fitted behind, and he hoped some day to lay the results before the Institution.

After a hearty vote of thanks the meeting terminated, most of the members adjoining to the Institution of Civil Engineers, where another meeting was in progress, a report of which follows.

Progress of Shipbuilding in Italy.

Proceedings were resumed also at the Institution of Civil Engineers at 10.30 A.M. on Friday, the 7th inst., with the President, the Marquis of Bristol, in the chair. The first business was the consideration of Colonel G. Russo's paper on "Fifty Years' Progress of Shipbuilding in Italy." It was read by Mr. R. W. Dana, the Secretary.

The paper began by paying a tribute to such men as Penn, Maudslay, Hawthorn, and Armstrong, and pointing out that they had amply repaid the debt owing by England to Italy for skilled assistance in shipbuilding which had been given in the sixteenth century. It then dealt with the general progress of the art in Italy from 1860, pointing out that although at that date there were about 100 yards devoted to the building of wooden ships, the industry rapidly declined in the early years of the period under review. Even after the introduction of iron for ship-work, the industry did not advance so rapidly in Italy as in some other countries, and in 1885 a policy of encouragement by means of subsidies or remission of duty on imported material was inaugurated. This policy of encouragement was still in operation. The paper gave some details of the various famous Italian yards, such as those of Ansaldo-Armstrong, Odero, Fratelli Orlando, &c. It also dealt with the progress of battleship design and construction, and discussed

* Vol. lxxxvii., page 810.

such famous examples and types as the Deulio, the Pietro Micca, the Italia, the Re Umberto, and the Regina Margherita. Some account of the Italian Registry of Shipping, the Registro Italiano, was also given, and a reference made to the schools of naval architecture and engineering at Genoa and Naples.

Sir William White opened the discussion. He said that it had been his good fortune to be associated for thirty years with the naval side of Italian shipbuilding, and that he had come to know many of the officers and constructors who had been responsible for it. He was glad of the opportunity of speaking of the pleasure and profit that that association, and the friendships he had made, had been to him. He had often been struck by the fact that the Italian naval constructors had always founded their designs on the basis of the strategy demanded by the physical and geographical features of their country. At the same time, in view of the fact that Italy was not a wealthy country, they had achieved quite remarkable results with the resources available to them. They had never been afraid to carry out what they thought were the best ideas, quite irrespective of what was being done elsewhere. In naval as in other matters there was frequently a tendency to follow a sort of fashion which happened to be set up, and he thought it a most valuable quality of the Italian naval authorities that they had never been afraid to think for themselves.

Signor Salvatore Orlando, President of the Italian Society of Naval Architects, regretted his inability to speak at any length owing to his imperfect knowledge of English, but said he would like to confirm the suggestion made by Sir William White that Italian naval work had been determined by physical and geographical requirements, by the fact that, although having such a great coast-line, Italy was not an island. He thought that the Italians, like the English, had a natural genius towards shipbuilding and navigation.

Admiral the Hon. Sir E. R. Fremantle thought that in its readiness to make experiments and new movements the Italian Navy had frequently made advances and given hints which were of great value to other navies. Sometimes it had made mistakes; but, on the whole, the world was very greatly indebted to it for the pioneer work it had done. Italian constructors had always been great believers in the value of experiment, which was, he thought, one of the reasons for their success.

Admiral Sir Reginald Custance said that he had not had an opportunity of hearing the paper read, but as he had been called upon, he would refer to a paragraph in it which he had noticed under the description of the Italia, in which it was stated that the principle of abolishing side armour was a failure on account of the unforeseen development of rapid-fire guns and high explosive projectiles. As it stood this paragraph was obviously not correct. If the principle referred to was right before the introduction of the quick-firing gun it must have been right after. Any changed conditions of gun-fire must apply equally to each party in a naval engagement.

Colonel G. Russo stated that the paper had been written at the invitation of the Institution, to whose proceedings he thought it an honour to contribute. He thanked Sir William White and others for the kind remarks they had made about Italy and Italian shipbuilding.

The President thought that the advances made and steps taken by Italy in certain directions showed that her developments were the joint work of the naval architect and the naval officer. The English naval officer had always taken a very close and keen interest in the doings of the Italian navy, and from his own career he remembered many incidents which illustrated that interest.

Progress in Naval Artillery.

The meeting then proceeded to the second paper, "Notes on Progress in Naval Artillery," by Sir Andrew Noble, which was read by its author. This paper, which we hope to reprint later, dealt with the gradual improvements both in guns and explosives which had taken place during the lifetime of its distinguished author. It was illustrated by wall diagrams dealing with old and modern artillery and with the properties of various types of explosives. These we shall also reproduce.

The discussion was opened by Rear-Admiral R. H. Bacon, who said that he was sure all present had listened to the paper with the greatest interest. All those who knew anything of the Navy would know that its members looked up to Sir Andrew Noble with a feeling which could only be described as one of veneration. To the naval officer the history of artillery was the history of Sir Andrew Noble.

Admiral the Hon. Sir E. R. Fremantle said he really knew nothing of the subject of the paper, but had found it of much interest. He thought the information and table with which it concluded giving data as to the amount of erosion due to different charges of much interest and importance.

Admiral Sir Archibald Douglas said that he looked upon Sir Andrew as the father of artillery, and what the Navy would have done without him he did not know. It owed the introductions of both the quick firing gun and cordite to Sir Andrew Noble.

Sir William White said that so far three naval officers had given their tribute to Sir Andrew Noble, and he would like to add to theirs one on behalf of the naval architects. There were four great names which stood out in the history of the development of artillery. They were Armstrong, Rendle, Vavasseur, and Noble.

Mr. Axel Welin said that all the previous speakers had been Englishmen, and that on behalf of Sweden he would like to add a word of thanks and appreciation for the great work which had been done by the author of the paper. The historical nature of the paper hardly gave a proper idea of the work which had been done by Sir Andrew Noble. Thousands of details had been worked out by Sir Andrew and his staff which had represented long years of work, and such details had by no means simply been left to the staff. Sir Andrew had himself taken a very close part in them all.

Vice-Admiral Luis Goni, of Chili, said that, as a representative from South America, he would like to add his tribute to the great work that had been done by Sir Andrew Noble. As long as thirty years ago they had had some of his guns in Chili, which had been of much service in an unfortunate war they had at that time; since then the progress due to Sir Andrew had been remarkable.

Sir Andrew Noble, in reply, said that he had now reached his eightieth year, and failing hearing, unfortunately, prevented him hearing very well the remarks which had been made on his paper. None the less, he thanked every one for their kind sentiments. He would like to mention that it was now sixty years ago since, on a voyage to the Cape of Good Hope, he first came to read the story of gunpowder. He was then so astonished by the varying reports that were given of the explosive pressure reached by it that he determined to investigate the matter for himself. He thought that since then he had found himself in an unusually favourable position for carrying out the work, and that anything he had done must be put down largely to good fortune.

The President, closing the discussion, said that those who were at the dinner on the previous evening would remember him saying that in Nature there were no rewards and penalties, only consequences. If this were true, he thought Sir Andrew Noble was one of the consequences. It was a pleasure to see Sir Andrew's amazing vitality, and he added his tribute to all that had been said before as to the wonderful work Sir Andrew had done.

Warship Building (1860 to 1910).

The next paper for consideration was that of Sir Philip Watts, K.C.B., on "Warship Building (1860 to 1910)." This paper, which was of considerable length, was taken as read, and there was no discussion on it.

Sir Philip, in his paper, gave a very comprehensive review of the development of each type of ship; but as machinery, armour, and artillery had been dealt with in other papers, there was little opportunity for dealing with the influences on ship design of contemporaneous progress in such work, so that there was not that wealth of deduction and analysis which we look for in contributions upon scientific questions from Sir Philip. Another deterrent was, no doubt, the determination of the Admiralty that official secrets regarding ships of the later types shall be scrupulously guarded, and obviously it would not have been courteous of Sir Philip to have entered upon any criticism of the ships of foreign Powers. Nevertheless, the paper is a most admirable *résumé* of the progress in size, engine-power, speed, and gun-power of the ships of practically all nations, up to the Neptune in the case of the British Navy, the Thuringen in the case of the German Navy, the Wyoming of the American Navy, and the Settsu of the Japanese Navy, and contemporary ships of other fleets. A similar *résumé* is given in the case of armoured cruisers, and Sir Philip established progress by indicating that when his late Majesty King Edward VII., then Prince of Wales, visited Canada in 1860, he made the passage in the Hero, a screw line-of-battleship of 91 guns and 2660 indicated horse-power, the time from Plymouth to St. John's being thirteen days under steam and sail; whereas, when His Majesty King George V. (when Prince of Wales) made the voyage to Canada in 1906, he went with the Indomitable, a ship of 17,250 tons, having eight 12-in. and sixteen 4-in. guns, machinery of 45,000 horse-power, and she made the return journey from Belleisle to Fastnet in three days, at an average speed of 25.13 knots. The later cruisers, torpedo craft, and submarine-boats were passed in review, the latest submarine vessels dealt with being the "D" class, of 595 tons displacement, with petroleum engines of 1200 horse-power, for driving the ship on the surface, and electric motors of 550 horse-power for propulsion when submerged. Sir Philip points out incidentally that, although it is not necessary for submarine vessels to be submerged to great depths, the U.S. Porpoise once accidentally touched bottom at a depth of 127½ ft. The great pressure prevented the ballast-tanks from being blown out by the air service, but after twenty minutes' hard pumping by the crew the boat rose unharmed to the surface. One of the earlier British boats once reached a depth of 78 ft. through too much water ballast being taken in. She was, however, brought to the surface undamaged except for a few leaky rivets. Since then one of the British "A" class has been submerged to a depth of 90 ft. Some interesting endurance trials have been undertaken at various times. In 1901 the French Narval was submerged for a twelve-hour test, but the crew suffered badly from the effects of the gas given off by the accumulators, which were not in a very satisfactory condition. In 1910 the Korrigan (France) and the Fulton (U.S.A.) both remained submerged for twelve hours, with no ill-effects to the crew, who came up fairly fresh at the end of these trials. Sir Philip Watts's paper is illustrated by a large number of diagrammatic elevations and plans to show the armour and disposition of the guns of all ships, but none of the ships of the British or German navies just laid down are included.

Armour for Ships.

The meeting then passed to the last paper, that on "Armour for Ships (1860 to 1910)," by Mr. Charles E. Ellis, which was read by the author. It was an historical paper, whose subject is obvious from its title. We hope to reprint it later.

The discussion was opened by Mr. C. H. Jordan, who said he had listened to the paper with great interest, but wished to point out that rolled armour was adopted on several of the early warships, including the Warrior. This was not altogether made clear in the early part of the paper.

Sir William White said that his connection with the armour question went back to 1864. He thought that the history of armour had shown that the manufacturers had always been willing to make expensive experiments and to take risks. Naturally they wished ultimately to be paid for such experiments, and he thought that on the whole they had been. The influence of the development of armour on naval architecture was enormous; as methods improved and thinner armour could be made to do the work of thicker, the process reacted on the size and arrangement of ships in all sorts of ways. He had now been out of direct touch with the question of armour for some nine years, and would rather like to know if Mr. Ellis could tell them anything of the development of the last few years.

Mr. C. E. Ellis, in reply, said that he would take note of the small point raised by Mr. Jordan. He was afraid the information asked for by Sir William White could not be given, for reasons which every one would understand. Before sitting down, he would like to express, for the manufacturers, their great indebtedness to the Admiralty for the assistance which had always been given them in experimental work dealing with armour.

Votes of Thanks.

This concluded the consideration on the technical papers, and the meeting terminated with votes of thanks to the Institutions of Civil Engineers and Mechanical Engineers for the loans of their halls, proposed by Sir John Thornycroft and seconded by Mr. Summers Hunter. The thanks of the

delegates were also expressed to the President and to the Institution by Maschinenbau-Oberingenieur F. Borowicka, of Austria-Hungary, and Mr. Stevenson Taylor, President of the American Society of Naval Architects. The thanks of the meeting were also passed to Mr. Dana, the Secretary, and his staff for the able way in which the arrangements for the Jubilee Meeting had been carried out.

River Excursion to the Port of London.

Upon the conclusion of the morning meetings on Friday a large number of delegates proceeded down the river, first with local steamers from Westminster to the Old Swan Pier, near Cannon-street Station, and thence by the saloon steamer Royal Sovereign, on which luncheon was served. The vessel made a trip down the river past the docks, so that the guests were able to see the extent of the harbour, and members of the reception committee explained the proposed developments under the new scheme of the Port of London Authority. The steamer went as far as Tilbury, where a special train awaited the company to take them back to Fenchurch-street Station.

Reception by His Majesty's Government.

On Friday evening, on the invitation of His Majesty's Government, a reception was given at the Savoy Hotel, and was very largely attended. The guests were received by the Right Hon. Walter Runciman, M.P., President of the Board of Education, and Mrs. Runciman, and the Right Hon. Reginald McKenna, M.P., First Lord of the Admiralty.

Visit to Windsor Castle.

The concluding function of the Congress was a visit paid to Windsor Castle "by command of His Majesty the King," on Saturday afternoon. The company, to the number of over 600, proceeded by special trains from Paddington to Windsor, and upon arriving at the Castle, were conducted first through the various rooms in the Upper Ward, where are located the State apartments and the King's private apartments, and later through the south wing, in which royal guests are accommodated. The company were entertained to tea and light refreshments in the gardens, and, owing to the excessive heat, the shade temperature reaching 86 deg., this part of the day was more appreciated even than the examination of the interesting features pointed out to the guests by the well-informed guides who took them in groups through the royal apartments. A photograph was taken of the gathering on the terrace, which will, no doubt, be cherished, especially by the foreign delegates and guests, as an appropriate souvenir of one of the most enjoyable international congresses ever held in this country.

INDUSTRIAL NOTES.

At the end of last week there was a distinct improvement in the aspect of affairs in connection with the dockers' and carters' strike in Manchester, for although business in Manchester and Salford was still greatly interfered with, there were no further disturbances. The grievances of both classes were under consideration by separate conferences, and it was stated that a provisional settlement had been reached in the case of the dockers and the Manchester Ship Canal Company. The offer of Mr. Askwith to try to promote peace negotiations in Glasgow was not accepted by the shipowners, who refused to recognise the men's union, although they have made concessions in wages. The employers in Leith have taken up the same position. The men on their side state that they will not consider any terms until the union is recognised. The presence of some 650 soldiers evidently had a controlling effect on the crowds at Salford, and consequently some amount of transport work was accomplished. A demonstration of about 2000 women took place in Salford on Friday last. They walked about 2 miles through the streets, hoping by their appearance to create sympathy with the dockers. They declared that they did not mind suffering, they only wanted the men not to give way. Of course, such demonstrations are meant to divert attention from the main points at issue, whatever the merits of these points may be. The dislocation of trade caused by the strike of seamen and firemen, followed by that of the dockers and carters, has been very costly. A rough estimate of the total loss at Hull is from 250,000*l.* to 500,000*l.* for a strike that lasted ten days, and flour advanced in price in the retailers' shops by from 60 to 80 per cent. At Grimsby the loss, though not so great, has been considerable, amounting, it is estimated, to about 1000*l.* Other ports have suffered correspondingly.

The beginning of this week, however, saw a settlement of the seamen, dockers, and carters' dispute, and on Monday morning it was known that the strikers had gained considerable concessions. The seamen and firemen have secured an advance of 10s. per month, and the shipowners have agreed that, in case of any dispute arising in future, they will meet the men and their representatives if they receive a reasonable notice. The crews, before embarkation, can have a doctor of their own choosing present when the medical examination takes place. With regard to the Federation ticket, no compulsion will be exercised on the men to take this out. The carters have got 25s. and 27s. per week respectively for one-horse men and two-horse men, instead of 27s. and 30s. per week, which they asked for, and they are to have 6d. an hour for all time worked before 7 o'clock a.m. Their trade union has also been recognised. The terms agreed to with the dockers are as follow:—(1) The minimum wage to be increased from 4s. 6d. to 5s. for a nine hours' day. Guarantees of a minimum of four hours when once a man has started work. (2) All men to receive 1s. 6d. as disappointment money if asked to work and then not allowed for some reason. Overtime rates from 6 p.m. to 8 a.m. to be increased to time and half. Double time for bank holidays or national holidays, and from Saturday midnight to Sunday midnight. (3) Increase from 5s. to 5s. 6d. for loading of general cargo. Increase from 4s. 6d. to 5s. for all shed men, casual checkers, and men discharging cargo. (4) The union is also to be recognised in cases where disputes arise, and the conditions of employment in many of the grades not mentioned above are to be greatly improved. The concessions made by the employers are very considerable, and the men are said to be well satisfied, and at once commenced to clear off arrears of work, but it is expected that at least a fortnight must elapse before the normal state of affairs is reached. The military and the extra police have been removed. The efforts of Mr. Askwith have been much appreciated.

The seamen's dispute in Rotterdam is settled, the men having decided to accept an increase of 5s. per month, conceded under certain conditions by the owners. The increase will not, however, take place till next year. In Amsterdam, mediation by the Dutch Minister of Agriculture and Commerce has been rejected by the shipowners, on the ground that a settlement brought about by this means would encourage men to consider that they had been justified in their methods of intimidation, and difficulties would be created.

The negotiations between the Midland Railway Company and the men employed in the goods department have, according to an official statement, resulted in a number of substantial improvements in the men's working conditions. The most important of these is the raising of the minimum wage of sidings porters from 16s. to 1*l.* per week, with a general increase of 1s. per week upon the maximum at various important stations. Horse-holders and point-holders at various centres are to have an increase of 1s. per week, and men are to be guaranteed a full day's pay for every period for which they are "booked on." An increase of 1s. per week has also been granted for under-shunters at St. Pancras, Bradford, Hendon, Somers Town, Sheffield, Cricklewood, Nottingham, Birmingham, Leicester, and some other centres. To goods shunters at various important sidings an eight-hour day is to be conceded during the summer months, and the gross hours of sidings porters are to be reduced from 12 to 10 hours per day. Work on Sundays, Good Friday, and Christmas Day is to be treated as overtime and paid for at greater rates.

The position in the Scandinavian labour market has not improved in the course of the week, and the prospects of amicable settlements have disappeared, both in Sweden and Norway. In the former country the masters accepted, but the men rejected, the proposal which was the outcome of the official mediator's endeavours, and the result is a lock-out, affecting 40,000 men within the building trades. The men held out for what was considered exorbitant pay, more especially in connection with piece-work; this pay has risen very materially for a number of years. Thus the hourly pay for a cement worker has risen from 35 or 40 öre to 64 öre during the last twenty years; that of carpenters from 25 or 30 öre to 55 öre during the same period; and for house-painters from 40 or 45 öre to 75 öre. The average pay of men in the building industry, for some length of time, has given cause for dissatisfaction, the reason being found in the frequent labour conflicts, in which respect the figures are exceptionally high, even without counting the four months' conflict in 1908, with a loss of 680,350 working days.

In Norway the miners appear to have almost unanimously rejected the masters' offer, and the lock-out consequently has come into operation as far as the first lot of 17,000 men are concerned. It has been stated that the large Sulitelma copper-mines in Northern Norway, which are owned by a Swedish company, are to be closed altogether; but this is not so. Owing to the large partial strike at the mines, it is not unlikely that the entire working will be closed for some time to come, and that a number of officials would thereby become superfluous.

A statement was made by Mr. Buxton in last Saturday's parliamentary papers that the total cost of the Labour Exchanges from the time the Labour Exchanges Act was passed to March 31, this year, in respect of salaries, travelling expenses, stationery, and the cost of buildings, was approximately 250,000*l.* The total includes capital expenditure in respect of premises.

A very interesting little emigration pamphlet has just been published by the Victorian Employers' Federation in Australia, giving particulars of the high wages ruling in trade and industry, and the scarcity of labour in the State. It is explained that the objects of the pamphlet are twofold. Firstly, by a statement of the actual facts to refute letters circulated in Great Britain by some of the local unions, reflecting on the wages paid out there, and alleging a scarcity of work; and, secondly, to encourage the emigration from Great Britain of suitable artisans with their families. It appears that very prosperous conditions now prevail in Victoria, and, indeed, all over Australia, and there seems to be a growing confidence in the political future—at any rate, to judge from the tone of the pamphlet. It is said that at the present time practically all manufacturing industries are undermanned in the State, and that, owing to the lack of labour, building operations are being limited, many Government contracts are unlet, and a great deal of work is either left undone or is being sent out of the State, and this in spite of the attractions of very high wages.

The immigration of rural workers and settlers from Great Britain is being encouraged by the Victorian Government, and the employers' federation maintains that artisan labour is being overlooked, although, as more new settlers are placed on the land, more workers will, no doubt, be required for manufacturing and other industries to supply the needs of an increasing population. As the country is opened up, the demand for artisan labour will, no doubt, continue to increase, and it is said that some British tradesmen who came to settle on the land found wages offered to artisans so high that they took up their trades again. In connection with Victorian industries, upwards of 15,782,648*l.* has been invested in machinery, land, and buildings; and, according to the statistics of 1909-10, there are now employed in these industries 97,355 hands, male and female. According to Government returns, there has in recent years been an average annual increase in the aggregate of wages paid amounting to 659,663*l.* As to wages, these, in all the main industries, are paid according to a scale determined by the wages boards, and there are about one hundred of these boards in operation. It is stated that the expense of living in Victoria is really very moderate, and compares favourably with any part of the world, both as to quality and cost. Bread costs from 5d. to 6d. per 4-lb. loaf; good tea ranges from 1s. to 1s. 6d. per pound; meat from 2d. to 7d. per pound; sugar, 3d. per pound; and old-age pensions are paid by the Government, the amount being 10s. per week, beginning at 65 years of age for men and 60 years of age for women. The rates of pay of the worker largely exceed those received by men in similar employment in Great Britain, and the hours as a rule are 48 per week, while in some trades they are down to 44 per week. Apprentices and improvers are said to be especially well treated, and the rates of pay in practice generally begin from 5s. to 10s. and 12s. per week, with half-yearly increases. There appears also to be a great demand for young people of both sexes in shops and factories, and also for female domestic service. There seems, therefore, to be many inducements to labour emigration to this State. The pamphlet contains a list of the Wages Board rates of wages for most trades, but we cannot include these here. Further information may be obtained on application to the Hon. Sir J. W. Taverner, Agent-General for Victoria, Melbourne-place, Strand, London, W.C.

The Royal Society of Arts.—At their meeting on Monday the Council of the Royal Society of Arts elected Lord Sanderson, G.C.B., Chairman for the year 1911-12. Lord Sanderson has been a member of the Society for over thirty years.

Acetylene as an Illuminant at the Coronation.—In connection with the illuminations at the recent Coronation a noteworthy feat was accomplished by the Thorn and Hoddle Acetylene Company, Limited, of 151, Victoria-street, S.W., which, at three days' notice, undertook the lighting of St. Edward's Tower and the whole of the west front of the Roman Catholic Cathedral at Westminster. The tower is 300 ft. high, and lights equivalent to 15,000 candle-power were fixed at its top.

THE "STOCK" OIL-FIRED CONVERTER AT DARLINGTON FORGE.

CONSTRUCTED BY MESSRS. THWAITES BROS., LIMITED, ENGINEERS, BRADFORD.

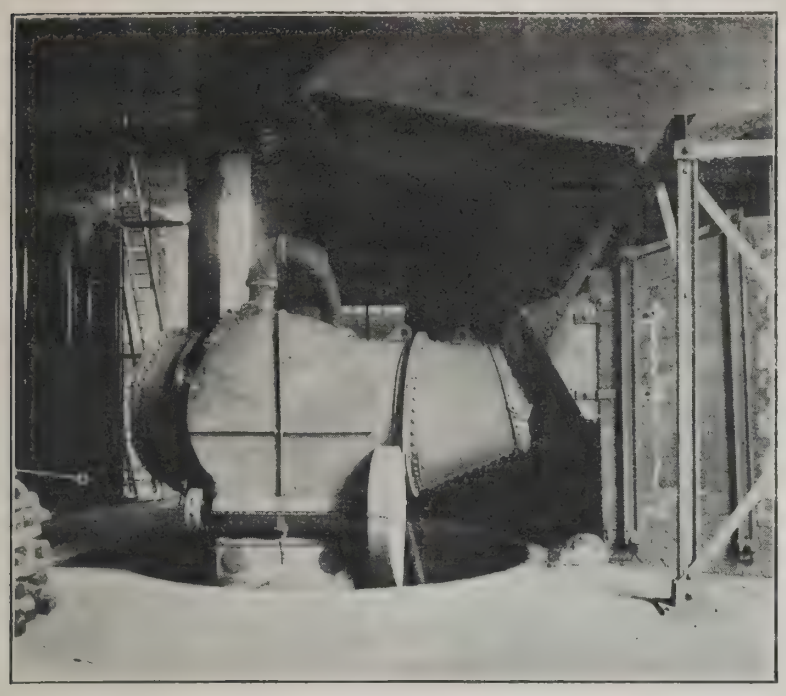


FIG. 1.

FIG. 2.

THROUGH the courtesy of the Darlington Forge Company, Limited, Darlington, we recently had the opportunity of inspecting a "Stock" oil-fired converter in operation at the firm's works, and were much struck with the simplicity of the plant and with the excellence of the steel castings turned out by it. The apparatus has now been in successful use for about twelve months at the Darlington Forge. It has been specially designed for the manufacture of all classes of steel, from soft-steel castings to special steels of the highest class. As will be seen from Figs. 1 and 2, above, the form of the vessel is very much like the ordinary Bessemer converter, so arranged that it can be tipped by gearing driven by electric motor, and also turned horizontally for charging and casting purposes. It is lined with ordinary silica firebrick, and is used not only for the conversion or blowing of iron, but also for melting the actual charge of iron and scrap by means of oil fuel, no separate cupola being required. The vessel is hung on trunnions, the bearings of which form part of the framing that revolves horizontally on the turntable shown. The trunnions work in roller bearings. The interior construction of the vessel permits of a large surface of metal being exposed to the action of the oil-burners, the section being oval. In front of the mouth of the converter are two hoods, one of which receives the hot gases of combustion during the melting of the charge (when the vessel is in a horizontal position) and leads them through a stove filled with iron pipes, through which air passes on its way to the converter. In this way the blast is heated up to about 300 deg. Cent. before it is used for blowing. When blowing the charge the vessel is vertical, and the gases are received by the other hood and conveyed by a chimney to the atmosphere. Before charging, the vessel is tipped to a horizontal position and is then turned through an angle of 90 deg. from the position it occupies when the melting is going on, in order that the mouth may project towards the charging-platform.

The charging (with about 3 tons of pig and scrap) is done by means of an ordinary peel, the operation being easily performed by three men in a little under 10 minutes. After being charged, the vessel is turned back through an angle of 90 deg. into the position necessary for melting, with the mouth pointing, as before stated, towards the air-heating chamber, which is a brickwork structure lined with firebrick. Fig. 1 shows it in this position. The air passing through the heater-pipes is supplied from a high-pressure Roots blower, the pressure being, when melting, about $\frac{3}{4}$ lb. per square inch, which is found sufficient for burning the oil, combustion being very perfect. The air is admitted in the side of the converter at two points on the side away from the heating-chamber, and at about one-third the height of the converter from the bottom, and at these two points the pipes that convey the oil are introduced. The time occupied by the melt with a 3-ton converter is about $1\frac{1}{2}$ hours.

In the converter which we saw at work there were two sets of oil-pipes, each set consisting of seven small steel tubes, each having an internal diameter of about $\frac{1}{16}$ in., and each set pointed through the centre of the tuyere where it was introduced. In this way the oil and the air are intimately mixed. We understand, however, that one set only of oil-pipes can be used if necessary. The oil used is the crudest petroleum available, costing about $2\frac{1}{2}$d. per gallon, and it can be easily stored in any large vessel, such as an old boiler. From this tank it is forced either by the blower or an air-compressor into a smaller tank, which contains a sufficient quantity of oil for from five to six meltings. In this service-tank is a coil through which hot air or steam circulates in order to regulate the viscosity of the oil. A small independently driven compressor is connected to this tank, which maintains a constant pressure of from 30 lb. to 35 lb. per square inch on the oil and forces the necessary quantity through a flexible pipe to the tubes in the tuyere-box. When the converter is cold, the gas and air are lighted by means of cotton-waste or similar substance; but when it has been heated up, this is not necessary, the temperature of the brick lining being of itself quite sufficient for the purpose.

TABLE I.—RESULTS OF TESTS ON SEVEN SAMPLES OF STEEL.

When the melting process is completed, the oil-pipes are withdrawn, an operation that can be carried out in a few seconds. After this, the vessel is turned into a vertical position, and blowing commences, the pressure of air being about $3\frac{1}{2}$ lb. per sq. in. It will be understood from what we have said that the air does not enter the converter from the bottom, and pass up through the molten metal, as in the Bessemer converter, but is blown down on the top of the metal. The blowing operation occupies from 15 to 20 minutes, so that a complete blow, including the charging and melting, occupies about two hours. Blowing being completed, the vessel is turned into the horizontal position it had when charged, and the mixings are introduced, the molten metal being afterwards stirred in order to incorporate the mass. The steel is then poured into a ladle, and casting commences. As an actual example of what we saw the following may be of interest. Charging commenced at 11.7 a.m., the weight of the charge being 2 tons 10 cwt., and the charge was melted at 12.49 p.m. The quantity of oil used was 65 gallons. Blowing commenced at 12.51 p.m. and finished at $1.10\frac{1}{2}$ p.m. The weight of the mixings added was 2 cwt. 2 qrs. 7 lb., which was proportioned for a steel having a 0.25 per cent. of carbon. The temperature of the blast was 215 deg. Cent., and the consumption of electricity for the whole process was 60 units. The whole plant is very conveniently arranged and is very compact.

The chief advantages claimed for it are: (1) That no cupola plant is required for melting, and the loss of iron in the cupola is saved. (2) That, as liquid fuel is used exclusively for melting, all risks of picking up impurities during the process are avoided. (3) The high temperature of the melted charge allows of the use of pig irons low in silicon, or the use of higher percentages of scrap. (4) The metal is in such a state of extreme fluidity that it is possible to make the most difficult and intricate castings. (5) The amount of space occupied is comparatively small, due to the fact that the vessel can be turned in the horizontal plane, so that the arrangements for charging, blowing, and pouring can be provided in any convenient position; and (7) the comparatively small amount of power required.

From what we saw at the Darlington Forge these claims certainly appeared to be substantiated, and as regards the cleanness and delicacy of the castings produced, there did not seem to be anything left to be desired. As to the actual cost of the process, based on the production of 52 tons of steel per week, working single shift only, taking hematite at 60s. per

ton and electric power at ½d. per unit, and including depreciation and interest, royalty charges, general repairs and upkeep, lining ladles, &c.; this, we are informed, works out at 4*l.* 17s. per ton.

On the previous page, in Table I., are the results of seven tensile and bending tests of cast steel produced by this process, and analyses are given in Table II.

A carbon tool steel has also been made containing 0.83 per cent. carbon, 0.072 per cent. manganese, 0.011 per cent. silicon, 0.011 per cent. phosphorus, and 0.011 per cent. sulphur, which forges well, and has, we understand, proved very successful for chipping and calking chisels and pneumatic tools. The process has also been used for high-speed tool steel, containing 0.627 per cent. carbon, 0.198 per cent. manganese, 0.059 per cent. silicon, 0.002 per cent. phosphorus, and 0.007 per cent. sulphur. A very low carbon steel, suitable for seamless solid-drawn tubes, which stood all the Admiralty tests, has also been made, the percentage of carbon being 0.08, manganese 0.18, silicon 0.011, phosphorus 0.011, and sulphur 0.01. These analyses show that practically any class of steel can be satisfactorily produced. A remarkable feature of the castings is the absence of blow-holes and other defects.

As an example of the punishment the steel will stand, the following may be mentioned:—A steel wheel, about 4 ft. 9 in. in diameter, was dropped edgewise on a steel ingot from the following heights—5 ft., 10 ft., 15 ft., and 20 ft., without showing signs of fracture. A drop of 40 ft. on the rim broke one spoke. After this four more drops of 40 ft. on edge caused no further fracture either to the rim or the spokes, and the wheel was finally broken up by a steel 3-ton ball dropped ten times on the boss from a height of 40 ft.

Some remarkably small thin castings have been made, one of them a cup, shaped like a wine-glass, 5 in. high, the cup part being 2½ in. in diameter and rather more than $\frac{1}{16}$ in. thick, and the stem $\frac{3}{8}$ in. Another was a tumbler 4½ in. high, 2¾ in. in diameter at the top, and 2¼ in. in diameter at the bottom, and of about the same thickness as the cup; while another casting (the frame of a Clayton radiator), 32 in. long, with a thickness of flange round the holes ⅛ in., and a thickness of body of $\frac{3}{16}$ in., was quite solid and free from blows. The carbon in all these was practically 0.2 per cent. The Darlington Forge Company have also cast some large stop-valves and pipes from steel made by this process. The plant is constructed by Messrs. Thwaites Brothers, Limited, Bradford.

THE SCIENTIFIC STUDY OF NAVAL ARCHITECTURE IN GERMANY.*

By Geheimer Regierungsrat Professor FLAMM.

IT may sound strange if, in the land of ships—the land that has probably done the most towards the practical and scientific development of the whole domain of shipbuilding—I take upon myself to describe the aims of scientific study in Germany, and the methods which it is now adopting. If, however, we reflect that, on account of the exceptionally rapid and accurate exchange of ideas which now takes place between the civilised countries of the world, every successive generation, as it springs up, finds it easy to avail itself of the whole of the material which the past and present fellow-craftsmen of all countries have collected, we see that all nations are thereby enabled to attain a similar development from the same bases, and to make similar advances in the various domains of engineering.

Apart from small unimportant beginnings, the real nursery for scientific study in the various domains of naval architecture in Germany has been the institution now known as the Königliche Technische Hochschule zu Berlin, in Charlottenburg. Since 1904 the Königliche Technische Hochschule in Dantzic has likewise taken part in this work. The naval architectural departments of both these colleges have the same end in view—namely, the training of the young men who will later in life take a successful part in the building of the mercantile and naval fleets of Germany.

In view of the high degree of interest which the Charlottenburg technical college, as a whole, has often aroused abroad, and especially in England, it may not be out of place to give a brief account of the arrangement of the course of study in ship and marine-engine building in the institution in question. In accordance with the system adopted in all the technical colleges in Germany, it is a preliminary requirement for the admission of the students that they should have passed the matriculation examination of a gymnasium, realgymnasium, or oberrealschule (establishments with the classical, classico-modern, and modern tendencies respectively, met with in English secondary schools). As these schools comprise nine forms, it follows that candidates for admission to technical colleges must be between eighteen and nineteen years of age. Since a further qualification is a practical training of one year at a shipyard of recognised standing, the age of the candidate is increased by six months, often by a whole year. To this must be added the period of military service, which is required of every physically and mentally sound German citizen, but which, in the case of an educated man who has obtained his volunteer certificate, is restricted to one year. For those who contemplate a career in the higher ranks of the Imperial naval construction department, the period of practical work and the year of service are spent in naval establishments—that is to say, in an Imperial dockyard and on board a naval training-ship respectively, before the course of study at the technical college is entered upon.

It may thus be said that the course of study begins when the student is twenty-one, and that it has been preceded by a certain period of preparation in the practical work of shipbuilding or marine-engine building. It is with young men thus prepared that the colleges at Charlottenburg and Dantzic have to reckon. The course of instruction is arranged in the following manner:—Within the department for naval architecture a distinction is made, in the first instance, between the professions of naval architect and marine engineer. The course of instruction itself in almost all the subjects comprises lectures and tutorials, or "practices," the object here kept in view being, that what is taught in the former is put into practical shape in the latter. It is a general principle in the German technical colleges that, as far as possible, no lectures are to be delivered without the accompanying tutorials. This principle extends, not only to the main professional subject in each case, but also to the subsidiary subjects, such as pure mathematics, mechanics, physics, descriptive geometry, political economy, law and administration, &c. It is to be observed that this principle has been productive of very good results, and that its extensive application has raised very considerably the standard of the education provided.

In all the departments devoted to different professional branches the course is a four-year one. At the conclusion of the second year, the preliminary examination for the degree or diploma is held, the final examination being taken at the close of the fourth year. The first two years are principally devoted to the more general studies in mathematics and natural science subjects, although a beginning is made with the introductory lectures and tutorials in the main subjects at the outset of the first term. But whereas the general subjects at first take up much more of the student's time than the special ones, this proportion gradually alters as the course proceeds till it finally becomes reversed. Another feature of the arrangement of the studies is that the lectures are, as far as possible, delivered during the earlier terms, while the drawing-office work gradually assumes greater importance as the course proceeds. This is intended to give the student in his last year as broad a base as possible for designing and applying what he has learned from the lectures.

In following out these ideas, the preliminary examination at the end of the fourth term is principally confined to the subject of mathematics, mechanics, physics, descriptive geometry, and chemistry, the special subjects being represented by the general details of marine engines and ships, while the results of the tutorials which, together with the mathematical proficiency shown, form the basis for the admission of the student to the oral examination, comprise a considerable number of constructive applications to details of vessels, such as double bottoms, afterbodies with rudders, &c., three sets of lines with the corresponding calculations of displacement, several exercises in connection with the theory of shipbuilding, and, finally, the design and calculation of a number of parts of machinery.

The primary object of the course of instruction during the first two years is to give the student a general grounding on the broadest possible lines in mathematics and natural science subjects, and concurrently therewith to introduce him to the elements of his special subject, so that, after passing the preliminary examination, he may devote himself in a higher degree to the direct study of his profession during the last two years. In the course of these two years, then, the tutorials gradually take the place of the lectures, and the professional study proper is gone into in detail. The student of naval architecture is engaged in designing and working out the plans of merchant and war vessels, and in studying the arrangement and working of shipyards, while the marine engineering student is at work on marine boilers, reciprocating, turbine, and internal-combustion engines. In addition, auxiliary engines and propellers are thoroughly gone into. Students in each branch concern themselves with the other just so far that, in their respective parts of the work on one and the same vessel, they can completely understand one another, and give due consideration to each other's requirements. The domain of airship construction and aerial navigation, which is closely related to naval architecture, has been included in the province of the latter, and it may be of interest to mention that quite a number of the first designers and engineers who have specialised in airship construction were formerly students in the department of naval architecture.

A programme of the subjects taken during the two last years of the course is given in the syllabus of the final examination for the diploma. Among these are included:—

SHIPBUILDING.

(*a*) Mercantile Shipbuilding:—
- (i.) Designing of ships' lines.
- (ii.) Complete design for a merchant vessel.
- (iii.) Outline plans for a merchant ship.

(*b*) Warship building:—
- (i.) Design of a warship.
- (ii.) Principal details in connection with the design.
- (iii.) Design of a propeller with accompanying calculations.
- (iv.) Questions relating to shipyard arrangements and work.

MARINE ENGINEERING.

- (i.) Design for a marine reciprocating engine or for a steam-turbine, together with boiler installation for a merchant vessel or for a warship.
- (ii.) Design for a marine gas-engine.
- (iii.) Design for a ship's auxiliary engine.
- (iv.) Outline plans for a merchant vessel.

The oral examination includes questions on:

SHIPBUILDING.

- (i.) Theory of ship construction.
- (ii.) Design and construction of ships.
- (iii.) Lay out and working of shipyards.
- (iv.) Construction and arrangement of warships.
- (v.) Marine engine construction.
- (vi.) Fundamental principles of law and administration.

MARINE ENGINEERING.

- (i.) Power plants, machine-tools and machine construction.
- (ii.) Marine engine construction (reciprocating, turbines, interoal-combustion).
- (iii.) Boiler construction, auxiliary engines and accessories.
- (iv.) Shipbuilding (merchant vessels and warships).
- (v.) Electricity as applied to ships.
- (vi.) Administration and management of naval and private establishments.

The Tables of Studies, with the times devoted to each subject, are given on page 55.

One of the important aims of science as applied to naval architecture is directed to the keeping of the rules of the classification societies in general accordance with the latest advances in knowledge. This refers chiefly to the arrangement, scantlings, and riveting together of the structural part of the hulls of vessels, and to the application of the laws of mechanics, statics, and dynamics. A second aim is that the rules of these societies, which are gradually gaining in authority, shall be prevented from developing into crystallised and inelastic ordinances, which interfere with the scientific development of ship design. We should insist, in this as in every other branch of engineering, that each new structure shall be looked upon much more as a concrete entity than has hitherto been the case, and that any new ship's design shall be worked out in this spirit.

The system of tabulating, still so much practised, according to which the peculiarities of a new vessel are taken account of only by a few parenthetic clauses and special rules, is not the one and only right method. The endeavour should be, more than formerly, to have the individual demands of a new vessel recognised to a greater degree than hitherto, even though they represent departures from the actual rules of the classification societies, if only reasonable justification can be shown for such departures. In the rules for the tonnage measurement, freeboard, and arrangement of bulkheads, every vessel should be treated individually to a far greater extent than hitherto, so that her lines and other features, in which the design as such is embodied, shall form the basis for determination of the tonnage, freeboard, and relative unsinkability, the stability and structural strength at the same time receiving due consideration. The result of this would be that persons entrusted with the judging and supervision of designs of new vessels, and those who at a later stage watch over the carrying of the rules into effect, would not, as is now too often the case, be men devoid of scientific training, such as retired sea-captains or others of this stamp, but thoroughly qualified engineers, who have been successfully engaged for a term of years in practical work. Comparisons with the conditions obtaining in other technical branches, such as those in bridge-building, engine-building, and electro-technical engineering, prove the correctness of these ideas as applied to the construction of ships—the more so as the navies of all the principal nations already follow the path marked out as a matter of course, and with complete success.

There is one other point to which I must here draw attention. Both for instructional purposes and for scientific research work, suitable laboratories are nowadays of the very greatest value. In all branches of engineering there are many questions the solution of which by pure analytical methods is impossible, and which therefore can only be dealt with by practical experiment. To what excellent use in this way have not the existing testing laboratories in almost all countries been put. At the Technical College in Charlottenburg the Mechanical Engineering Section in particular has established numerous laboratories, and they have been of the utmost value both from the educational and from the industrial point of view. The distribution of these laboratories among the different sections of the college is as follows:—

Section for	Architecture	1
,,	Civil Engineering	1
,,	Mechanical Engineering	9
,,	Shipbuilding and Marine Engineering	—
,,	Chemistry and Metallurgy	8
,,	General Science	1

It will thus be seen that the Technical College at Charlottenburg now possesses twenty laboratories, which serve the purposes of the research work of the professors as well as those of instruction. A short time ago a project for the installation of a second laboratory for the civil engineering section for the investigation of hydraulic questions was unfortunately rejected by the Prussian House of Representatives. It is a remarkable circumstance that in the entire establishment the section for shipbuilding and engineering should be the only one which has no laboratory. It must be admitted that this is very much to be deplored, and that the course of instruction as well as the solution of engineering problems is immensely impeded thereby. It may readily be understood, therefore, that the naval architectural section is doing its best towards the early attainment of an establishment of this kind so as to close up the gap in its

* Paper read at the Jubilee meeting of the Institution of Naval Architects, July 6, 1911, and illustrated by cinematographic views.

TABLE OF STUDIES (CHARLOTTENBURG).

First Year's Course. For all Students.

Subject.	Number of Hours per Week. Winter.	Summer.
1. Experimental physics	4	4
2. Physics laboratory	4	4
3. Higher mathematics	8	8
4. Mechanics (I.)	6	6
5. Descriptive geometry (I. and II.)	8	8
6. Elements of machine design	6	6
7. Elements of ships		
8. Mechanical technology (I.) and metallurgy	2	2
9. Outline of experimental chemistry	2	2
10. Introductory to ditto	2	2
11. Ship drawing (I.)	2	2
12. Elements of political economy	4	4
13. Tutorial work in testing laboratory		1

structure. What may be accomplished in such an establishment by the aid of a private grant is shown in my book on "The Screw Propeller and its Action on Water." It may not be uninteresting to outline some of the experiments made, and illustrate them by cinematograph views. The conclusions to which my researches have led are briefly these :—

1. The screw propeller in general exerts a sucking action upon the water, which lowers the surface of the latter.

2. The sternward-flowing stream preserves an approximately cylindrical form ; a propeller which draws together or heaps up the water does not exist. The water from the screw-propellers of canal-boats accordingly does not injuriously affect the beds of the channels ; this has been established by more than 4000 experimental runs made with model twin-screw vessels 23 ft. in length in a model canal-sectioned tank in the Royal experimenting establishment for hydraulic engineering and shipbuilding in Charlottenburg. In the case of a single-screw vessel, the observed effect on the bed of a channel was found to be entirely due to the interposition of the stern-post and rudder behind the propeller. The downward diversion of the water from the propeller and consequent action upon the bottom of the canal ceases at once when a pair of side-rudders are substituted for the single rudder at the centre-line. This latter fact was also demonstrated in the Charlottenburg establishment.

3. Axial thrust almost completely ceases as soon as the powerful suction effect brings air into the space about the screw-propeller. If the water above the propeller be covered over so that no air can get down beside the latter, exceedingly high efficiencies are obtained with blade-tips working close to the surface, this being quite impossible without such covering.

4. The axial thrust has its maximum value at the instant when cavitation begins.

5. The "thudding" effect of the propeller on the stern of a vessel is not the result of the projecting of masses of water against the hull, for no direct blow is thus delivered ; it may be that the smallness of the space in which the propeller has to work in the vicinity of the hull tends to produce a vacuum into which the water rushes in the intervals between the passage of successive blades. In so far as the vibrations of a vessel are due to propeller action, they are caused by the sucking down of a certain quantity of air by each successive blade in passing (accompanied by a loss of thrust) ; while the lower blades, which are meanwhile well immersed, produce a sudden and very pronounced displacement of the centre of pressure of the issuing stream, and a moment is set up which is very probably one of the causes of the vibration of the after body.

6. The loss of speed of turbine vessels in a heavy sea may also be similarly explained by the fact that the propellers are in the first place heavily loaded, so that the sucking action per unit of blade surface is at its maximum, and they are accordingly very likely to draw in air. Then, when the vessel pitches, a quantity of air is pretty sure to be drawn in during the passage of the blade near the surface of the water, whereby the thrust is almost destroyed, and the speed of the vessel is diminished.

If these ideas prove to be correct, it will be necessary in designing ships' propellers to pay more attention than hitherto to the form of the leading or suction surface, and, as in the case of the blades of aeroplane propellers, to have the smallest radius of curvature of this just behind the leading edge.

The stream of water which comes in contact with the convex side of the movable surface does not repel that side, but sucks it directly towards itself. If, then, the surface be held fast, the stream of water must be subjected to motion in the contrary direction and, in the case of a propeller blade, produces a thrust upon it.

My endeavours are directed to the establishment of a suitable naval architecture laboratory in which experiments may be made on this action of the screw propeller, and in which the gross and net amounts of work done by the latter, *i.e.*, its efficiency, may at the same time be determined. Further experiments will then be made to determine the effect on each other of several screw propellers arranged abreast, or one behind the other, and also the effect exercised on them by the rudder. We shall then know whether it is possible to design high-speed propellers of high efficiency, and our knowledge over a wide range of under-water phenomena will be available for further advances in this branch of engineering.

Students should take part in all inquiries of this kind, so that the results may benefit succeeding generations of engineers and enable them to play a leading part in the scientific progress of their time.

SOME FURTHER NOTES ON CAVITATION.*

By S. W. BARNABY, Member of Council.

ON the occasion of our last International Congress in 1897 I read a paper on "The Formation of Cavities in Water by Screw Propellers at High Speeds."† This was a restatement of the theory of cavitation which had been brought before the Institution of Civil Engineers by Sir John Thornycroft and myself two years previously. In order to prevent the formation of these cavities we proposed to limit the thrust per square inch of projected surface to about 11¼ lb. per square inch in the case of propellers having approximately the same shape of blade and pitch ratio, and the same depth of immersion as those of the destroyer Daring. It was explained that somewhat higher pressures than this could be allowed for screws of finer pitch ratio, or having deeper immersion, or for screws in which the shape of the blade departed from the ellipse, being made broad at the tips. At the time this limit of 11¼ lb. pressure per unit of surface was suggested the use of turbines for marine propulsion was not contemplated, and it has been found, as might have been expected, that the uniform turning moment obtained with a turbine enables a higher thrust to be used. In the case of a direct-driven propeller, where it is necessary to submit to some sacrifice of screw efficiency, in order that the turbine may run at a sufficiently high rate of revolutions for economical working, a thrust of about 13 lb. is accepted, and found to give a good compromise, although I believe that incipient cavitation is then present, causing an increase of slip, because the revolutions usually exceed by 2 or 3 per cent. the number which would be estimated from the tables based on model experiments.

It will be noticed that, in addition to this more uniform turning moment, all the conditions suggested in the paper referred to as likely to permit of the use of a higher thrust than 11¼ lb., are present in the turbine propeller as now made. For example, the tips of the blades usually have much greater immersion than in the screws driven by piston engines, because of their small diameter; also the pitch ratio is very fine ; and, lastly, the area is thrown as much as possible out towards the tips of the blades. I also pointed out some years ago* that the thrust of propellers driven by four-cycle explosion engines should not exceed 8 lb. to 9 lb. per square inch, because, unless a large number of cylinders are employed, the very irregular turning-moment of these engines causes cavitation to occur at lower thrusts than in the case of double-acting steam-engines.

I refer to this because some criticism has lately been expressed concerning the accepted theory of cavitation, on the ground that it had been proved that some propellers would stand a higher thrust than 11¼ lb. without cavitating, and that some cavitated at a much lower thrust. It is a mistake to suppose that 11¼ lb. was intended to apply to all cases. It has been suggested that the peripheral velocity of the propeller is a better criterion of the approach of cavitating conditions than thrust per unit area. I will give my reasons for not concurring with this view. The peripheral velocity at which cavitation commences is not by any means constant, but varies both with pitch ratio and "abscissa" value or slip ratio to a much greater extent than does thrust per square inch.

In Table I., page 56, are shown the cavitating speeds of three-bladed turbine-driven propellers, having a developed area of 0.74 disc area, assuming a limiting thrust of 13 lb. per square inch of projected area.

In Table II. I give the peripheral velocities of the same screws at these cavitating speeds, and it will be seen that they vary from 4,800 ft. to 17,280 ft. per minute.

I have drawn a thick line round those figures in the table which lie within the limits of usual turbine practice, that is, I include pitch ratios lying between 0.8 and 1.0 and "abscissa" values lying between 9 and 13. Within these circumscribed limits the peripheral velocities only vary from 10,550 ft. to 15,000 ft., and this probably explains why an impression has been formed that peripheral velocity is a safe guide in the design of turbine screws, an average value of about 12,000 ft. being recommended. This corresponds with an "abscissa value" of 11 and a pitch ratio of from 0.9 to 1.0, which are about the conditions usually aimed at, and so far it would be correct to design for this tip speed, provided the developed area of the blade was about that given in the table. But if the blades are made wider than this—if, say, they have a projected area of 0.75 disc area instead of a developed area of 0.74 disc area, which latter is the area ratio used in Tables I. and II.—then the peripheral velocities may be considerably increased.

In Table III. I have worked out the peripheral velocities for this projected surface ratio within the same limits of "abscissa value" and pitch ratio. They range from 11,600 ft. to 15,900 ft. per minute.†

The peripheral velocity of the wing screws of the destroyer Tartar, which had this projected area ratio of 0.75, was 14,850 ft. per minute. Very much lower velocities than these would have to be employed for propellers driven by geared turbines at lower revolutions, because, as will be seen from Table II., the permissible tip velocity decreases rapidly with increase of pitch ratio. On the other hand, a thrust of 13 lb. to 14 lb. would be equally suitable for direct-driven or geared propellers.

Commander C. W. Dyson, U.S.N., in a very interesting series of papers containing a large amount of valuable information on the trials of United States warships which he has contributed to the proceedings of the American Society of Naval Engineers, states that thrusts as high as 16 lb. per square inch of projected surface have in certain cases been recorded in turbine propellers giving a fair amount of efficiency. This is so much higher a thrust than I have ever known to be put through a screw with good results that I think it possible Commander Dyson may have a different way of calculating the thrust. In any case, it is not exactly measurable, and depends on the estimate which is made of the value of the propulsive coefficient and of the thrust deduction. He also states that the thrust per unit of projected area does not appear to be so important as the thrust per unit of disc area in affecting efficiency.

I think the explanation of the improvement in efficiency

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 6, 1911.

† Transactions of the Institution of Naval Architects, vol. xxxix., page 139.

* "Marine Propellers," Fifth Edition, page 58.

† The assumptions made are 10 per cent. wake and 10 per cent. thrust deduction, 50 per cent. propulsive coefficient, 85 per cent. blade correction ; projected area = 0.75 disc area ; thrust, 13 lb. per square inch.

which he finds accompanying a reduced pressure per unit of disc area is that turbine propellers are nearly always made of two small a diameter for good efficiency in order to get high revolutions for the turbines, and the efficiency of the propeller would almost always be improved by increasing the diameter and reducing the revolutions, but at the expense of the combined efficiency of screw and turbine.

Mr. D. W. Taylor, in the book he has just published on "Speed and Power of Ships," contends that the accepted theory of cavitation is inadequate, and that tip velocity and shape of blade section are the prime factors involved. There is no doubt that both have a very important influence on cavitation, and especially the latter. Mr. Taylor is so competent an experimenter and so high an authority on all matters connected with propulsion that one would hesitate to question any opinion he may express on any subject coming within the scope of tank inquiry; but it is well known that propellers cannot be made to cavitate in a tank under ordinary conditions, and very special means have to be taken to get the phenomenon to exhibit itself with model screws.

Mr. Parsons was able to observe it in a special tank with heated water having a vacuum over the surface, and it will be remembered that he confirmed generally the results I had obtained by calculation.

Mr. Taylor has not followed this method, but has made experiments with a special form of blade which cavitates freely in cold water, and with the pressure of the atmosphere upon the surface; but the instrument he used could hardly be called a propeller, because it is far outside the limits of all existing practice. The pitch ratio is as fine as 0.3, and the blades are unusually narrow and thick. Now, even at 0.6 pitch ratio the efficiency of a propeller has dropped from a maximum of 0.74 to 0.58, and no propeller has ever been made, so far as I know, with so low a pitch ratio as 0.3, because under such conditions it is simply churning the water. This model cavitates so vigorously that the thrust becomes negative above a moderate number of revolutions, and if used as a propeller it would only need to be driven fast enough to actually reverse the direction of the motion of the vessel.

Cavities first begin to appear at as low a tip speed as 3000 ft. per minute, and the thrust becomes negative at a tip speed of between 5000 and 6000 ft. With this special "cavitator" Mr. Taylor has been able to measure the pressure at different parts of the face and back of the blade by means of a very ingenious arrangement of pressure gauges, and he has found that there is a reduction of pressure at the leading edge of the driving face of his blade, and he expresses the opinion that cavitation is only injurious when it occurs at the driving face.

It seems to me that this conclusion has been arrived at somewhat hastily, and requires much further proof before it can be accepted. I think the reduction of pressure which was observed on the driving face was due to the abnormally fine pitch ratio in conjunction with a thick and narrow blade, and I do not think it is possible for cavities to form on the driving face with ordinary pitch angles and blades of normal section.

The photographs taken by Mr. Parsons of his propeller when cavitating, under conditions properly representing those found in practice, show most clearly that the cavities are at the back of the blade. (See Fig. 2, above.)

I thoroughly agree with Mr. Taylor that it is of the utmost importance that the blades should be very thin at the leading edge, and it may be even advantageous to make the edge thinner than will stand the water pressure unsupported, and to stiffen it with circumferential ribs, as he recommends; but I do not think he has made out a case in favour of taking tip velocity as a criterion in preference to pressure, because he has himself shown that cavitation will under special circumstances begin at as low a velocity as 3000 ft., and I have shown that in the case of the Tartar the tip velocity was as high as 14,850 ft., with good results. It will be observed that Mr. Taylor's cure for cavitation is the same as my own—namely, very wide blades—although he arrives at it by a different line of reasoning. He thinks that "face cavitation begins to spread slowly with increase of tip speed, so that the wider the blade the greater the area of the face whose thrust is not nullified by cavitation." As already stated, I doubt the existence of face cavitation on a properly-designed propeller, although it can evidently exist on an instrument specially designed to cavitate; and I still think that the great waste of power admittedly caused by cavitation is due to cavities at the back of the blade, and that these affect the efficiency, because at least half, and usually the major portion, of the thrust is due to the suction of the blade back, and this is lost as soon as the water breaks away from the back. Sir John Thornycroft has suggested to me that efficiency is also probably affected by the fact that when cavitating the propeller is working in a medium of less density, because the air bubbles extracted from the water forward of the screw form part of the stream passing through the screw's disc, as clearly shown by the spirals in the photographs (see Figs. 1 and 2), and thereby reduce its density.

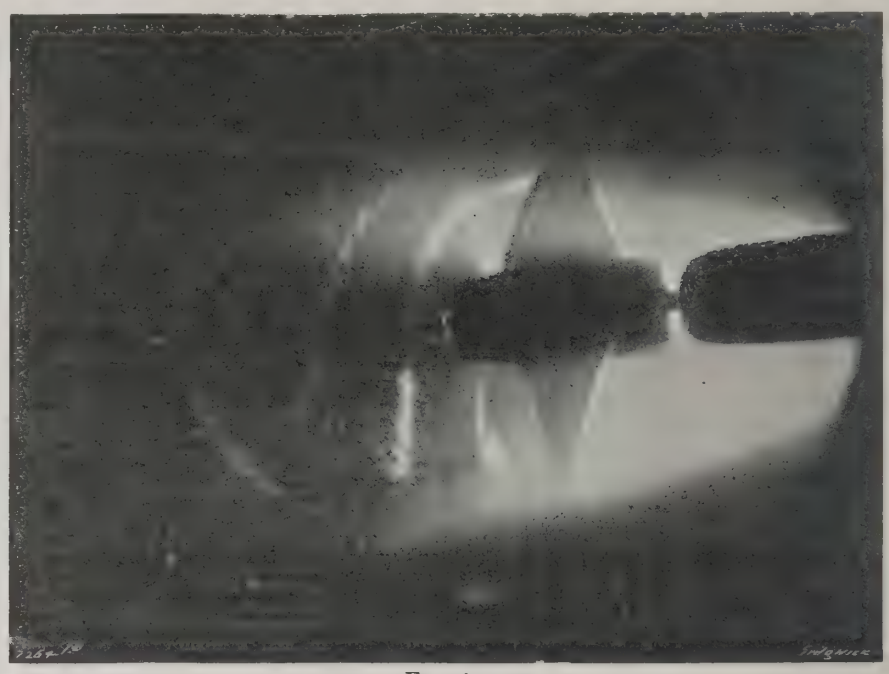

FIG. 1.

FIG. 2.

It may be objected that I bring forward no fresh proof that thrust is a safe guide, and that the tip velocities I have given in the tables are based on the assumption of a fixed limit of pressure. This is quite true, and perhaps further experiment only can settle the question. I must, however, say I have found it a very satisfactory method of fixing the blade area, and have seen no reason to doubt the soundness of the theory on which it is based.

I am glad to learn that Mr. Parsons is making a special tank of a much larger size than that with which he made his previous experiments, but arranged to work under the same conditions of hot water relieved of the atmospheric pressure, in which he will try models of actual propellers, and I think judgment should be reserved until the results he obtains are made known.

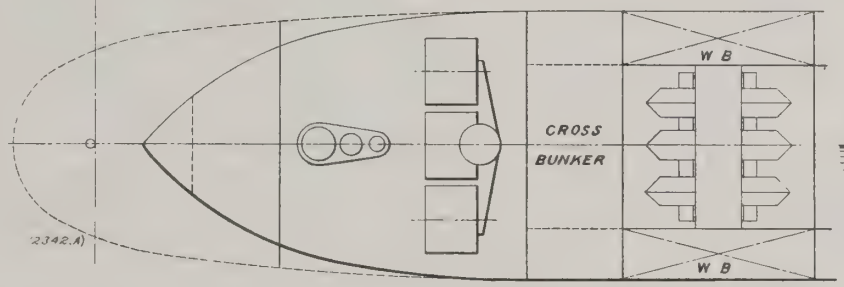

Fig. 4.

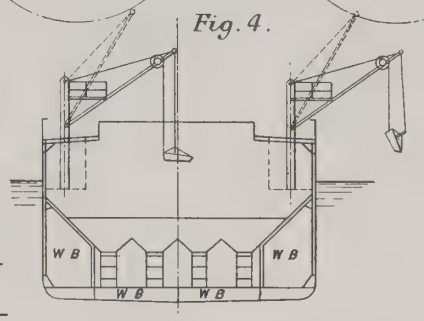

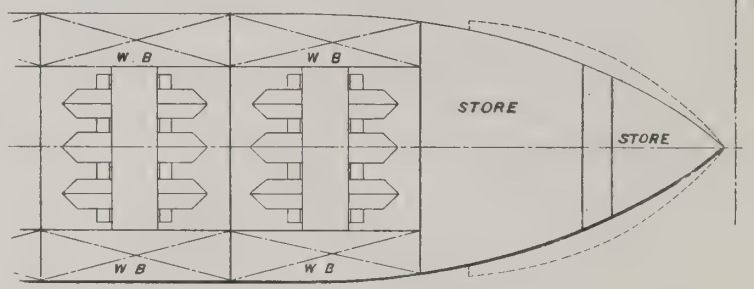

RECENT DEVELOPMENTS IN THE SEA TRANSPORTATION OF SWEDISH ORE.*

By J. JOHNSON, Member.

THE iron ore trade of Sweden having in later years grown into comparatively large proportions, it was found necessary, in order to keep pace with the increasing output of the mines, to facilitate the loading capacities at the shipping ports by means of suitable viaducts, enabling the ore to be shipped by utilising the force of gravity, with a minimum amount of manual labour.

The Port of Narvik, in Norway, over which most of the Swedish ore is now shipped, furnishes an example of the best facilities of its kind in Europe. The largest ships at present engaged in the ore trade can be loaded with reasonable despatch at this well-sheltered natural harbour.

Turning our attention, on the other hand, to the vessels employed in this trade, we find that these are nearly all ordinary tramp steamers, of which those that are specially built for the trade have as a distinguishing feature a special outfit of a large number of ordinary steam-winches, with accompanying masts, derricks, and gear of a very heavy description.

In the best-planned vessels of this kind the arrangement of hatches has enabled the cargo to be better distributed, in order to somewhat reduce the straining action on the ship's structure.

Special care has to be exercised in protecting watertight parts of the structure, such as ballast-tank tops and shaft-tunnels, from the falling of the heavy ore, when loading, by means of extra heavy ceiling, which in a comparatively short time is impregnated with the grit of the ore, and consequently adds an appreciable amount to the equipped weight of the vessel as well as to the cost of upkeep.

The discharging is still done chiefly by manual labour, the ore being shovelled into iron buckets of varying shapes, which, when filled, are hoisted by the winches in the usual way and emptied into shoots, lashed on the deck for the purpose. By means of the said shoots the ore is run into barges alongside the discharging vessel. This procedure is in vogue in most of the Continental ports, such as Emden and Rotterdam. In some of the British ports, receiving Swedish ore in

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 6, 1911.

smaller quantities, the hoisting is effected by means of cranes on the wharfs. Shovelling iron ore by hand is extremely laborious, and it is plain that such a method of discharging is not in keeping with the improved facilities at the mines and at the best-equipped loading ports.

Naturally, one's attention is turned to the latest systems of discharging ore in the United States of America, where heavy and expensive staiths are fitted for the purpose and equipped with powerful clam-shell buckets, whereby the ore is handled effectively and with great despatch.

The main conditions of the American ore trade differ, however, considerably from the corresponding conditions in Europe. The American ore trade follows certain permanent interior routes, reducing the number of discharging ports to a few, whereas the number of European ports receiving ore is comparatively large. The consistency of the American ore is entirely different from that of the Swedish ore. Consequently, if any improvements are aimed at in the shape of mechanical devices for discharging iron ore of a stony nature and high specific gravity, such contrivances will have to be carried by the vessels themselves employed in the trade.

With a view of constructing a vessel for the purpose of carrying ore, specially fitted out with mechanical means of discharging, the Johnson-Welin system was devised a few years ago. By this system the ore is carried in bins or pockets of iron, built into the ship and placed athwartships, having sloping bottoms with suitable outlets.

The Trafikaktiebolaget Grängesberg - Oxelösund, of Stockholm, owners of the principal iron-mines in Sweden, decided to try this system, and in 1907 a temporary bin, holding about 130 tons, was fitted on board the s.s. Polcirkeln, belonging to a sub-company of the above-mentioned mining company. The results proved satisfactory, and in the following year the said company decided to build a vessel of about 8000 tons deadweight capacity to be fitted out with bins on the Johnson-Welin system.

By reference to Figs. 1 to 4, page 57, representing the general arrangement of a steamer designed in accordance with this system, it will be seen that the cargo hold is sub-divided by means of transverse bulkheads, forming alternately bins for the cargo and discharging shafts. The vertical bulkheads do not extend to the bottom of the hold, but terminate about 7 ft. from the tank top, and are connected to the sloping bottoms of the bins. These sloping bottoms have an inclination of 42 degrees from the horizon.

The ore is discharged from the bins through specially constructed shoots, having a closing arrangement, which can be manipulated by one man. Figs. 5 and 6 show the mechanical principle of this closing arrangement, which is quite simple, and has been found to work very satisfactorily. The door A consists merely of an iron plate, stayed by two horizontal stiffening bars. This door is raised by means of a lever C, having an adjustable counterweight E. The shaft F conveys this motion to the other side. The upper edge of the door A is held in position and guided by links D. The fulcrum F of the levers C and the point of suspension of the links D are in such positions that in opening the outlet the door A move outwards, thus relieving the pressure of the ore.

CLOSING ARRANGEMENT FOR ORE SPOUT

Fig. 5.

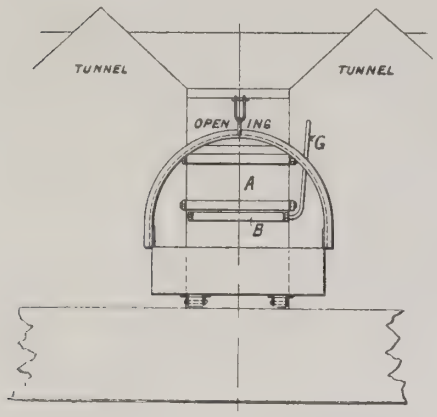

Fig. 6.

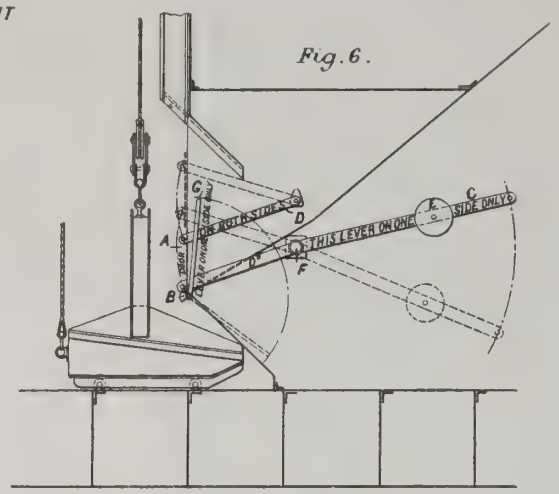

Fig 7
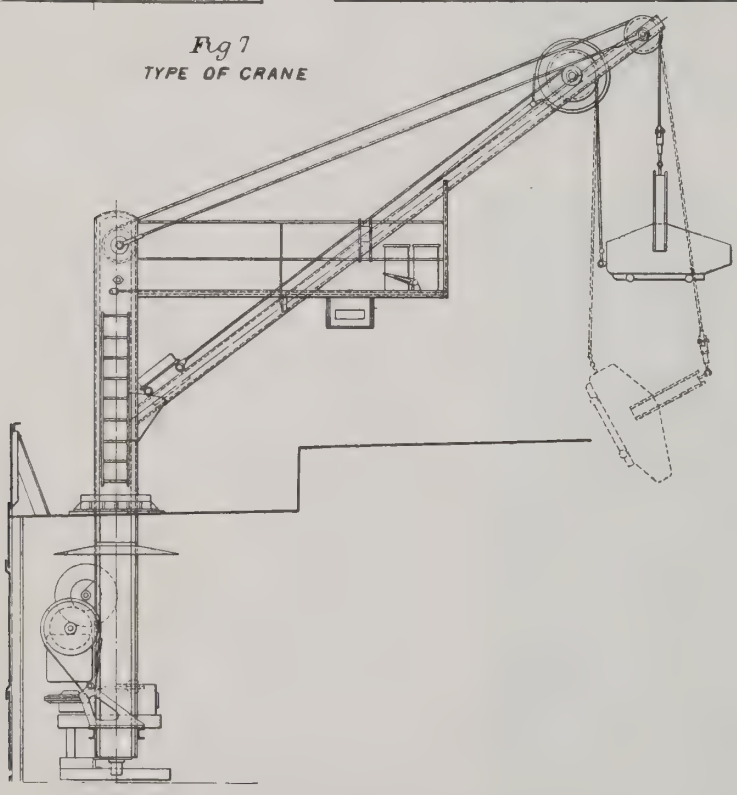
TYPE OF CRANE



At the bottom of the shoot an angle-iron lip B is fitted, actuated by a lever G; this lip B serves the purpose of stopping the outflow of smaller particles of ore if the door A cannot be entirely closed. The design of the vessel in this case embodies wing tanks for carrying water ballast, and the tops of these wing tanks, as will be seen from the section in Fig. 4, page 57, are sloping, in order to convey the ore to the wing outlet shoots. No wood ceiling is required in the holds, with the exception of protective wood cleading on the sloping sides of the wing ballast tanks in way of the cargo bins.

In working out the preliminary design, it was decided that cranes should be used for lifting the cargo out of the holds, and it was further decided to adopt electrical transmission of power for driving the cranes.

The decision to use cranes for the hoisting of the cargo was an outcome of the necessity of dispensing entirely with all hands on deck, except the crane-driver, and the design of these cranes must therefore embody several special features, not usual in ships' cranes. In the first instance the crane-driver must not stand at the rear of the crane, but on a platform in front, where he can look down into the hold when the crane is swung inboard, and be in an equally advantageous position to overlook the emptying of the bucket when the crane is swung outboard.

It was further decided that the tilting of the ore discharging buckets must be effected by the crane-driver, without any assistance whatever from men on the deck or on the receiving barges, and, in order to carry this out, it was arranged to suspend the buckets by means of two ropes, one hoisting and one tipping rope, these ropes to be wound on separate drums of equal circumferential speeds, and when the bucket is to be emptied the brake is put on the tippling rope, leaving the bucket suspended by that rope in an incline position, at any required height.

Fig. 7 shows the design of crane ultimately adopted in conformity with the above-mentioned requirements. The crane builders in this case adopted an independent drum for the tipping rope, actuated automatically by a counterweight, which travels on the jib of the crane. The hoisting, slewing, and tipping is all done by one man on the platform of the crane, and the electric transmission of power lends itself admirably to the smooth and effective working, which has been a noted feature in the cranes of the two vessels built on this system.

During the coldest winter months the ore, on its way from the mines, is sometimes mixed with ice and snow and is apt to freeze together in the holds of the vessels, thus rendering the discharging very difficult.

Steam heating pipes were therefore fitted in the holds under the bottoms of the ore bins for preventing this freezing, which arrangement has proved satisfactory.

Two vessels have been built on this system, the s.s. Vollrath Tham, of 8000 tons carrying capacity, in 1909, and the s.s. Sir Ernest Cassel, of 10,800 tons, in 1910. The contracts for building both these vessels were entrusted to the well-known firm of Messrs. R. and W. Hawthorn, Leslie, and Co., of Hebburn-on-Tyne.

In both these steamers the electric generating plant for power and light is situated aft in the engine-room 'tween decks, each vessel having a very complete outfit, comprising two duplicate compound engines, each coupled direct to a multipolar compound-wound generator, and one lighting set.

In the Vollrath Tham ten electric cranes are fitted, each having a lifting capacity of 2½ tons at a speed of 75 ft. per minute. In the Sir Ernest Cassel twelve cranes are fitted, each having a lifting capacity of 3½ tons at a speed of 75 ft. per minute. In this vessel the crane construction admits of changing the radius, thus enabling the cargo to be discharged into barges or on railway wagons at varying distances up to 20 ft. from the ship's side. All the mechanism of the cranes is below deck in watertight compartments. The time used in discharging each of these two vessels is about 36 hours with all cranes working. The primary object in view has, however, not been so much the reduction of time of discharging as the diminishing of manual labour.

In Continental ports, where the ore is discharged with ordinary winches into barges, twelve men are considered necessary at each hatch:—One man at the hoisting winch, one man at the slewing winch, two men on deck directing the winch men and manipulating the tilting of the buckets, and eight men in the hold. Thus, in an ordinary vessel of the same loading capacity as the Vollrath Tham using steam-winches, 120 men would, as a rule, be employed, taking about 40 hours for discharging. In the Vollrath Tham 20 men are sufficient.

The same ratio holds good in the Sir Ernest Cassel, that is, 24 men do the same work as 144 men discharging by hand and with ordinary steam winches, in the latter case using, of course, considerably more exertion.

The Vollrath Tham and Sir Ernest Cassel, have, during continuous service, fulfilled all expectations of their owners, designers, and builders. The vessels have been built to the British Corporation Class, and it is a great pleasure to record the enthusiasm and skill displayed during the construction by the classification society, the builders, and sub-contractors.

THE HISTORY OF THE INSTITUTION OF NAVAL ARCHITECTS AND OF SCIENTIFIC EDUCATION IN NAVAL ARCHITECTURE.*

By Sir WILLIAM H. WHITE, K.C.B., F.R.S., LL.D., D.Sc., D.Eng., Hon. Vice-President.

(*Concluded from page* 15.)

As was natural, the admission of marine engineers to membership in 1869 led to reconsideration of the title borne by the Institution. The desirability, or otherwise, of indicating explicitly in its title that the Institution is a common centre for both marine engineers and naval architects having been considered, it was unanimously decided to continue in use the title under which the Institution had risen from small beginnings, to a place in the front rank of technical societies. For more than twenty years there has also been in existence an Institute of Marine Engineers, whose membership chiefly consists of men charged with great and increasing responsibilities incidental to the management of the complex machinery in modern steamships, so that the question of title may be regarded as unlikely ever to be raised again, and there is obviously no reason for raising it.

Enlarged experience, of course, may lead to further modification of the rules, but as they stand they represent the matured views of the Council. They have been embodied in the Charter of Incorporation, which has been granted recently to the Institution by His Majesty in Council, and which forms a fitting recognition of the work done for the British Empire and the profession represented in our society during the first half-century of its existence.

The office of treasurer to the Institution is of consider-

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 4, 1911.

able importance; and during the somewhat protracted period when the finances were not very flourishing, it was no sinecure. An eminent Thames shipbuilder, Mr. Samuda, served in that capacity from 1860 to 1885, and was succeeded by Mr. H. Green, then head of another famous firm of shipbuilders and shipowners. Mr. Morgan—one of the Chief Constructors at the Admiralty and an original member of the Institution, as well as a student of the second School of Naval Architecture—served from 1891 to 1903, when ill-health compelled him to resign. Dr. Elgar was elected as treasurer in 1903, and continued in that office until his sudden death in January, 1909. Full acknowledgment of the long and faithful service which Dr. Elgar had rendered to the Institution was made in the Transactions for 1909. His splendid generosity, both during his life and at his death, will ever be kept in memory, making him the greatest benefactor to the Institution who has yet appeared. An admirable successor to Dr. Elgar was found in Mr. Dixon, Chairman of Lloyd's Register of Shipping, but death again brought loss to the Institution speedily, and the present treasurer, Mr. Charles Ellis, was then elected by the Council. In his hands the finance of the Institution is well cared for, and its condition has long been satisfactory. Much of the success attained has undoubtedly been due to the ability and energy displayed by the secretaries to the Institution, of whom there have been six during the half century of its existence. Allusion has already been made to the work done by Sir Edward Reed in the preliminary arrangements connected with the organisation and start of the Institution. This work he did as honorary secretary. To no man ought more grateful acknowledgment be recorded than to him for the establishment of this society. But it is proper to associate with that acknowledgment due recognition of the valuable assistance rendered by others at that stage, and especially by Mr. Scott Russell and Sir Nathaniel Barnaby. The latter is naturally reticent in regard to his own work at the beginning; his unceasing devotion to the interests of the Institution is too well known to need any detailed comment. In regard to Mr. Scott Russell, Sir Nathaniel Barnaby permits me to use the following extract from a note written at my request for information in regard to the initial stages of our organisation:—

"The formation of such an Institution had been talked about by members of the first school of naval architecture, and then by Dr. Woolley and members of his school. It needed someone familiar with the working of other great technical associations to bring such mere wishes to a living issue. In Mr. Scott Russell a leader was found, and a most capable leader he was."

Sir Edward Reed served as the official secretary and editor of the Transactions from the first meetings of the Institution up to April, 1862, when increasing professional engagements and official responsibilities caused him to resign. Provision for performing the secretarial duties was then placed in the hands of an executive committee consisting of Dr. Woolley and Mr. Scott Russell, who soon after appointed an assistant secretary. By special resolution of the Council the services of Sir Edward Reed were suitably acknowledged, and he was elected a Member of Council, so that his further help in the conduct of the affairs of the Institution was ensured, and for many years was generously rendered. In 1864 Mr. C. W. Merrifield, F.R.S. (Principal of the Royal School of Naval Architecture and Marine Engineering) became acting-secretary, and from 1867 to 1875 he served as honorary secretary. From 1871 to 1874 Mr. Merrifield was aided in the secretarial duties by an able assistant-secretary, Mr. Adrian Vizetely, who had been one of the few comparatively British private students at the Royal School of Naval Architecture. On the death of Mr. Vizetely, Mr. Adam Woolley succeeded him as assistant-secretary, and in the following year was appointed secretary on the occasion of Mr. Merrifield's retirement. As one of his old students, and having had intimate personal knowledge of the great services which Mr. Merrifield quietly and without reward rendered to the Institution at a time when its finances were in an unsatisfactory state, I desire to place on record this simple acknowledgment of what we owe to him. Mr. Woolley resigned in 1878, and Mr. (now Sir) George Holmes was appointed secretary. He held office for 23 years, and greatly aided the remarkable developments of the Institution which took place during that period. His resignation was consequent on appointment to the Chairmanship of the Board of Public Works in Ireland. Our great indebtedness to him was recognised by the presentation of an address, accompanied by more substantial tokens of the high appreciation by all classes of what were well described as "invaluable services as Secretary of the Institution." Sir George Holmes was also appointed an honorary member, and still maintains an active interest in the welfare of the Institution he served so long and well.

It is unnecessary to dwell upon the work which has been done since his appointment in 1901 by our present secretary, Mr. R. W. Dana. Like his predecessor, Mr. Dana has been trained as an engineer; he is a member of the Institution of Civil Engineers, and relinquished active practice to take up this position. Possession of professional qualifications such as these are of great advantage to the Institution, whose Transactions are edited by the secretary, and to these qualifications are added personal qualities which have enabled Mr. Dana to succeed in the necessarily difficult task of following so efficient a predecessor. It is to be hoped that his service with the Institution will be as long as that of Sir George Holmes, and that it will be associated with equally great developments in members and prosperity.

Qualifications of Professional Members.

Before dealing with the growth of the Institution, it may be of interest to describe briefly the conditions which have been laid down from time to time for the admission of professional members. The corresponding conditions for associates have already been stated, and have remained unchanged from the commencement.

According to the original constitution the class of members was to "consist exclusively of naval architects," although the founders recognised that there were then "comparatively few naval architects in this country." In the statement made by the secretary at the preliminary meeting the following passage occurs:—

"Many of our shipbuilders are not naval architects; consequently the members will not be numerous for some years to come."

With wise prescience it was added: "One of the earliest and best effects [of the Institution] will doubtless be the stimulation of shipbuilders to a great improvement in their mode of training young men, and this will react in favour of the Institution by increasing the number of persons eligible for membership."

This prediction was not fulfilled as speedily as was hoped for, notwithstanding vigorous action taken at an early date by the Institution to encourage the education of naval architects; but it has come true increasingly in later days, and now gives the best assurance we possess of continued and increasing prosperity for the Institution. As the years have passed the professional education of naval architects has been continuously and greatly improved, and the Council has steadily raised the standard of qualification for admission to the class of members. Notwithstanding this action the growth of numbers in that class has been both great and comparatively rapid, and this is a matter for satisfaction.

The names of eminent marine engineers appeared amongst the little group of founders, and in the first roll of the Institution. These men concurred both in the title selected for the Institution and in the restriction of membership to naval architects, and took their place contentedly in the class of associates. In that list were included representatives of many other branches of engineering, but the prominent part taken by marine engineers in the promotion of the scheme was good evidence of their intimate association with naval architecture. In fact, some of these gentlemen — Scott Russell, for example — practised in both marine engineering and shipbuilding. It was natural, therefore—indeed, was almost inevitable — that both these two closely allied branches should be represented before long in the class of members. This step was taken in 1869; its wisdom has been demonstrated by subsequent events. Since that date "marine engineers conversant with naval architecture" have been admitted to membership, after their claims have been approved by the Council at successive general meetings of the Institution. Actual election, of course, rests with the members. The present rules also provide that a candidate who "has been regularly educated by apprenticeship or pupilage, or in a technical school as a civil or mechanical engineer, and has been subsequently professionally employed for at least seven years in some public or private shipbuilding yard or marine engine works," may be admitted to membership if his claim is approved by the Council, and he is recommended for election. Formerly the lower limit of age for membership was twenty-five years; it is now thirty years.

In 1899 a class of associate members was established. It is intended to provide for admission to the Institution of naval architects and marine engineers who are less than thirty years of age, subject to the conditions that their professional training has been of a satisfactory character, and that they are actively engaged in professional work. This class also provides for properly trained men who are over thirty, but still occupy positions which do not involve such a degree of responsibility as is required for full membership. In 1910 there were 169 associate members on the roll of the Institution; in future that number will become much larger. Many men who originally entered the Institution as associate members have since been transferred to full membership.

Another modification of the original constitution was made in 1905 by the establishment of a student class into which are admitted young men between eighteen and twenty-five years of age who are serving as articled pupils, apprentices, or students in naval architecture or marine engineering. Before attaining the age of twenty-six years students as a rule apply for transfer to the class of associate members, and usually have that transfer approved unless their training is considered by the Council to be inadequate. Experience gained during the last six years shows that the student class will in future become a good recruiting ground for members.

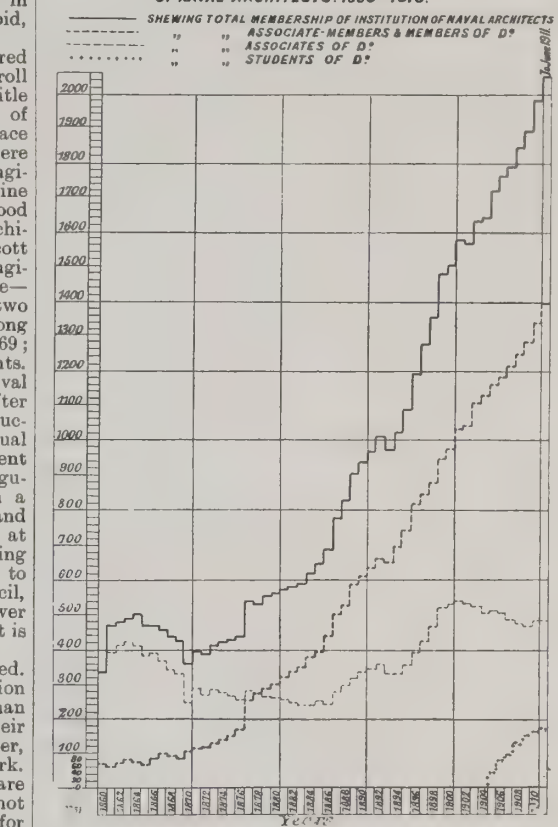
At present the special committee appointed by the Council has under consideration the desirability or otherwise of amending in some respects the professional qualifications which shall be required in future for the admission of members and associate members, especially in view of the great developments made during recent years in the specialised branches of engineering whose products form so important a part of the equipment of modern steamships. In these and other ways the Council makes a constant endeavour to promote the true interests of the Institution and to secure a high standard of qualification amongst those admitted thereto.

Growth of the Institution.

Attention will next be directed to the development of the Institution since its foundation in regard to numbers on the roll. The facts are diagrammatically represented in the annexed chart. The first list of names published in the first volume of the Transactions showed a total of 324; it did not distinguish between members and associates. Classification was commenced in 1861; there were then enrolled 10 honorary members and honorary associates, 65 members and 390 associates. The members' list embraced almost all the leading officials in the shipbuilding department of the Admiralty, as well as a considerable number of the leading private shipbuilders, and the principal surveyors of Lloyd's Register of Shipping. In the list of associates stood the names of a large number of men who were eminent for public services, of distinguished officers in the Royal Navy, of leading engineers, shipowners, yachtsmen, and others interested in ships and shipping. These lists are well worth study; they furnish ample evidence of wide-spread sympathy and support given to the Institution by representatives of many departments of public life and work at this early stage of its existence.

The list for 1864 showed a total of 492, of whom 75 were members. During the next six years there was a serious falling-off in the number of associates, which was only 240 in 1870 as against 409 in 1863. The total number on the roll in 1870 was 351, only 27 more than in 1860, although the members had increased to 103, or nearly 60 per cent. in the ten years. This increase in the professional class continued slowly, and by 1876 there were 168 members but only 249 associates. Probably an explanation is to be found in the fact that the great excitement of the period 1860-65 in connection with discussions connected with the ironclad reconstruction was followed by a period of reaction and that the Institution was settling down to no less important but less attractive technical work which had been the main purpose for

CHART SHEWING MEMBERSHIP OF THE INSTITUTION OF NAVAL ARCHITECTS. 1860 - 1910.



which it was established. Falling off in numbers also involved lessened financial resources, and this could be ill afforded.

In 1877 the first summer meeting of the Institution was held at Glasgow, the invitation having been given by the local authorities of that city and district as well as by the principal firms of shipbuilders and engineers on the Clyde. This meeting was necessarily experimental, but it proved to be a complete success. The ebb-tide in the affairs of the Institution was turned; the immediate effects were an addition of fully 50 per cent. to the list of members, and 10 per cent. to that of associates. The total names on the roll rose to 537, the previous maximum (attained in 1864) having been 492. It was thus made evident that the prosperity of the Institution might be increased by holding similar meetings in the great centres of shipbuilding and shipping, and so extending public knowledge of the work and objects of the Institution. Those of us who took part in the first of these meetings can never forget what the Institution owes to our friends on the Clyde, and in particular to the late Mr. William Denny, who had recently been elected to the Council, and took a conspicuous part in organising the arrangements.

The Glasgow meeting was succeeded by nine years of steady growth in membership, and a progressive diminution in the number of associates kept the total numbers down—in 1885 that total was 642, the associates being 241 and members 390. A summer meeting at Liverpool next year was most successful, but it left the associate class untouched. No considerable increase in numbers occurred until 1887, when a summer meeting was held in Newcastle-on-Tyne and Sunderland. On that occasion the list of members was increased by 63, and that of associates by 27. The personal influence of Lord Ravensworth (then President) in the district no doubt contributed to this satisfactory result; but, undoubtedly, the main cause of increase was that better knowledge of the Institution which followed upon its visit to the North-East Coast. Since then many other summer meetings have been held—at Glasgow twice

(1888 and 1901), Cardiff (1893), Southampton (1894), Newcastle-on-Tyne (1899), Belfast and Dublin (1893). In nearly all cases an increase of membership has followed upon these meetings. In the first twenty-five years of the history of the Institution the total number first enrolled was not quite doubled; the number on the roll in 1885 was more than doubled in 1898. The total membership is now (June, 1911) 2047, of whom 480 are associates; 1401 members and associate-members, and 166 are students. Obviously the associate class needs large additions to strengthen this branch of membership.

Relations to Kindred Societies.

When this Institution was founded there were only one or two local associations of shipbuilders existing in the United Kingdom. Of these that in Glasgow was the most important. It has since been merged in the Institution of Engineers and Shipbuilders in Scotland, and has joined in the friendly greetings we have received when our visits to Glasgow have been made. In later years there has been a considerable increase in local associations formed for the study and advancement of shipbuilding and marine engineering. When that local development began fears were expressed lest the Institution of Naval Architects should suffer from consequent competition. My own opinion has always been that the real effect would be in a contrary direction, and it has been my pleasure to assist in the formation of local societies which are now flourishing. Experience has since demonstrated conclusively that there is room and scope for all the associations. Local societies can and do meet more frequently than the parent institution; they afford excellent opportunities for an interchange of information and for discussion; their Transactions already form valuable supplements to those of the Institution of Naval Architects. Our Institution can still secure an adequate, and often has a redundant, supply of excellent papers. Relations of the most cordial character have always existed, and still exist, between our Institution and these local associations, which have been our generous and kindly hosts whenever summer meetings have been held at British seaports. In many instances membership of local associations is a prelude to membership of the Institution of Naval Architects; in other cases membership of the Institution of Naval Architects has been supplemented by membership of local associations; not a few presidents of local associations have also served on the Council of the central Institution. There is, in short, no conflict, but rather a community of interests and mutual help in the effort to advance knowledge of science and practice amongst shipbuilders and marine engineers.

The relations existing between the Institution of Naval Architects and foreign societies of a kindred nature are also most friendly. This was to be expected in view of the facts that these foreign societies have been modelled largely on lines laid down for this Institution, and that they have benefited by our longer experience. Amongst their chief organisers and founders have been prominent gentlemen who were previously valued members of this Institution, which may, therefore, be fairly described as the "parent" institution, in relation to those which have been established during the last twenty-five years. First, in 1888, came the Association Technique Maritime with its seat in Paris. Its first president was our distinguished honorary member, the late M. de Bussy; its second the late M. Daymard, who for many years previously had been an active and much respected member with us. The name of its present president, M. Emile Bertin, has long been on our list; for fifteen years it has stood amongst our honorary members. The invitation to visit France in 1895, and the complete success of the Paris meetings that year, were largely due to M. Bertin, and his services to the Institution will not soon be forgotten.

In 1893 the American Society of Naval Architects and Marine Engineers was incorporated at New York, avowedly to undertake in the United States work similar in character to that which had been done in this country by the Institution of Naval Architects for more than thirty years. Amongst the prime movers in this enterprise, of which the success has been great, were found naval architects and marine engineers who were members of our Institution, some of whom had received their professional education in Great Britain.

The Schiffbautechnische Gesellschaft was founded in Berlin in 1899. Its president, Professor Busley, and many of the members of the society are also members of this Institution. Japan and Sweden have each established a Society of Naval Architects, in which members of this Institution take a leading part. Italy has a similar society, of which the president (Signor Orlando) and many of his colleagues have long been valued members of this Institution. It is no exaggeration, therefore, to claim that the influence of our Institution on the foundation and organisation of these societies has been great, and the fact has been repeatedly acknowledged. This important portion of our work lies outside the scheme which our founders constructed, but it is no discredit to them that they did not foresee its possibility. By establishing and maintaining cordial relations with foreign kindred societies the Institution of Naval Architects has undoubtedly furthered the more rapid advancement of scientific methods in connection with shipbuilding and marine engineering throughout the world, and has itself been greatly benefited by the addition to its roll of many distinguished foreign members and associates. Their presence and collaboration have been and always will be highly esteemed.

The list of meetings abroad is not a long one. All these gatherings have proved most pleasant and successful; and the institution owes much to gentlemen who have undertaken the responsibility for their organisation. The first was held at Paris in 1895; the second at Hamburg and Berlin in 1896; the third at Düsseldorf in 1902, when it took the form of a joint meeting with the German society. The last foreign meeting was held at Bordeaux in 1907 in connection with an international exhibition and a congress of naval architects, in the organisation of which M. Bertin took the leading part. Kindred societies of all countries were represented on that occasion, and our president (the Earl of Glasgow) was appointed to be president of the congress.

This international side of the work of the Institution received one of its most successful illustrations when the congress of 1897 was held in London. Delegates from all the principal maritime countries attended, as they are doing on this occasion, and the programme of papers was of exceptional interest. His Majesty King Edward VII. (then Prince of Wales) honoured the Institution by becoming president of the congress, and receiving our guests from abroad, Her Majesty Queen Victoria graciously invited members of the congress to Windsor, and personally welcomed the foreign delegates. Now that the celebration of the Jubilee of the Institution has been undertaken, we desire to emphasise once more its international character by giving a hearty welcome to foreign friends and professional colleagues; as well as by including in the record of progress in shipbuilding and marine engineering, not merely the history of what has been accomplished in the United Kingdom, but of what has been done throughout the world during the memorable half-century over which the existence of our Institution has extended. The programme of papers to be read and discussed indicates that this intention has been fulfilled; the volume in which these contributions will be collected will, undoubtedly, be not merely interesting historically, but valuable to all maritime nations.

The Education of Naval Architects.*

One of the main objects in the minds of the founders of this Institution was the provision, as soon as possible, of adequate arrangements for the scientific as well as the practical training of young men desirous of becoming naval architects and marine engineers. It was their desire to remove the reproach that no school of naval architecture and marine engineering existed in the United Kingdom, although it was the country which held the lead in shipowning and shipbuilding. At the preliminary meetings this subject received attention, and no long time elapsed before definite action was taken to bring the subject before the Government. At the meetings in March, 1863, Mr. Scott Russell read a paper which represented not merely his own view, but those of his colleagues on the Council. No better advocate could have been found for pleading the cause; the object of technical education was one in which Mr. Scott Russell had done valuable pioneer work, his own reputation as an experimentalist in some branches of scientific research was considerable; and—as the builder of the Great Eastern and a man whose influence had been great on the design of the Warrior—he was able to command the attention of the Government as well as that of his fellow shipbuilders. The action taken by the Institution was both well considered and prompt. A committee was formed, representations were made to the Government, and the movement was greatly aided by Lord Hampton and by Sir Edward Reed (who had been appointed Chief Constructor of the Royal Navy). Before the year 1864 ended the Royal School of Naval Architecture and Marine Engineering had been organised, the Admiralty and the Education Department having joined in the arrangement of its courses of study and the selection of the teaching staff. That school continued to carry on its work at South Kensington until 1873. During that period 119 students were under instruction. Of these, 95 students—53 naval architects and 42 marine engineers—completed their training. Fourteen students came from foreign countries, and 24 were British private students. The Institution of Naval Architects watched over its child with great solicitude, every annual report containing references to its progress. Prominent members of the Institution gave their services as lecturers and teachers, and in that list appeared names which will always be esteemed great in the history of ships and shipbuilding. Sir George Airy, the Astronomer Royal, lectured on the errors and corrections of compasses in iron ships; Mr. William Froude on stability and oscillations. Professor Rankine on strength of materials and propulsion of ships; Dr. Percy on metallurgy; Scott Russell on fluid resistance and the wave-line theory for ship forms; Sir Edward Reed and his principal assistants in the Admiralty on subjects connected with ship design and construction; and distinguished officers of the Royal Navy on questions of naval armaments and tactics. Dr. Woolley, who had been principal of the second British School of Naval Architecture, was appointed to supervise the courses of studies, and acted as chief examiner. Mr. Merrifield (already mentioned) was the first principal; with him were associated an excellent staff of teachers, which included some of the most brilliant younger graduates of Cambridge University, as well as members of the constructive and engineering staff at the Admiralty, and practical shipbuilders and marine engineers of large experience. It is not possible for me to speak impartially of an Institution where I was taught my profession, and afterwards became a teacher myself; it would be out of place for me to say much about the results attained. These results speak for themselves, for the men who were trained at South Kensington are now nearing the end of their professional careers; their work is chiefly done, and its results are known. In its whole career it is probable that the Institution of Naval Architects has done no more important piece of work than that involved in the establishment, organisation, and development of this third British School of Naval Architecture. In a certain sense the effort may be thought to have been made too soon. The amount of support which the school received from private British shipbuilders and engineers must undoubtedly have disappointed the expectations of its founders, and to that extent been "before its time." On the other hand, the establishment of this school removed the long-standing reproach that the United Kingdom absolutely neglected the scientific education of its naval architects and marine engineers. Moreover, when its doors were closed, those of the Royal Naval College were opened, and in that splendid educational establishment, from that time onward, the lamp of scientific instruction in shipbuilding and engineering has been kept steadily burning. This later work has been done under the patronage of the Admiralty, and primarily for its purposes; but it has also been made available for the teaching of private students who were properly qualified to gain admission, and not a few of those educated there for the service of the Admiralty are now holding positions of great responsibility in private firms.

Some years elapsed before any other institution in Great Britain provided advanced courses of instruction in naval architecture and marine engineering, but the advantages of such instruction were being more and more realised in the interval, and the time was ripe for action when Mrs. John Elder generously provided the means for establishing a Professorship of Naval Architecture in the University of Glasgow. Dr. Elgar was appointed to this Chair in 1884, and organised the courses of study with the ability which his training at South Kensington and subsequent professional career had led his friends to anticipate would be displayed. His successors at Glasgow, the late Professor Jenkin and Professor Biles, both received their training under the Admiralty, and have fully justified its merits in their subsequent work. The Glasgow classes have been well filled, and have attracted many students from abroad, as well as from the United Kingdom, and it had become evident that larger provision for the education of young naval architects and marine engineers were required before further steps were taken to secure it at English Universities. Fortunately, this want has now been met, and professorships of naval architecture have been established at Newcastle-on-Tyne and Liverpool. The former is due to the joint action of the authorities of Armstrong College and of the leading private firms on the North-East Coast; the second to the generosity of Mr. Alexander Elder. In these cases, also, the two Professors—Welch and Abell—received their training at the Royal Naval College. For many years it was my endeavour to secure the establishment of these two Chairs, and the fulfilment of that hope, although long deferred, has been most gratifying. It is certain, however, that unless there had been a growth of belief in the advantages attaching to this higher instruction amongst shipbuilders, shipowners, and marine engineers in this country, these results would never have been obtained, and that growth has undoubtedly originated from the seeds sown by this Institution nearly fifty years ago.

The Institution has watched with sympathetic interest all these recent educational developments, and meanwhile has been at work in other directions. Scholarships have been established in aid of young men whose means are limited. One of these was founded by subscriptions from the members in order to perpetuate the memory and services to the Institution of the late Mr. Martell (Chief Surveyor of Lloyd's Register of Shipping). Another was founded by the generosity of the late Dr. Elgar, and bears his name. A third is due to the action of our respected Vice-President, Mr. Alfred Yarrow. It is reasonable to suppose also that the example and influence of action taken by the Institution may have had some effect on the minds of the Chairman and Committee of Lloyd's Register of Shipping, who have established a considerable number of scholarships for the benefit of students of naval architecture and marine engineering at the universities above named. Successive chairmen of that committee have been vice-presidents of the Institution, the names of many members of the committee are on our roll, and the professional staff are very largely represented in our membership. While fully recognising that the generous deed is entirely due to the committee, the Institution may feel that it is not entirely disconnected therefrom.

Public Work Done by the Institution.

Immediately after its foundation the Institution of Naval Architects began work of a public character in relation to shipping. It continues to do this work either by means of special committees appointed by the Council, or through representatives and delegates nominated by the Council, as members of committees appointed by Government departments or public bodies. Lord Hampton was of great service in bringing into prominence the fact that important work of this nature was undertaken by the Institution, and his presidential addresses were full of allusions to the subject. Questions relating to the lading and stability of merchant ships engaged attention from the Institution long before the Load-Line Committee, appointed by the Board of Trade in 1884, under the chairmanship of Sir Edward Reed, began an inquiry which eventually led to regulations that are now international in their application. The basis of that settlement was found in proposals which had been previously placed before the Institution by Mr. Martell, and freely discussed by members and associates, shipowners naturally holding strong opinions on the subject.

The Board of Trade, through its Marine Department, has again and again availed itself of the services of the Institution, asking for opinions on important points or requesting the nomination of representatives on com

* For further details on this subject see the address given by the writer as Chairman of the Royal Society of Arts on November 18, 1908.

mittees, special and standing. At present the Institution is thus represented on the advisory committee which deals with questions affecting shipping interests, as well as on another committee of longer standing, which advises on technical details of ships and machinery. Members of the Institution have served on special committees which have dealt with tonnage laws and other important matters affecting the mercantile marine.

Lloyd's Register of Shipping has also sought the aid of the Institution, which has long had representatives on the Technical Sub-Committee of Lloyd's, and quite recently has been invited to appoint representatives on the General Committee.

The British Corporation has requested and received similar assistance from the Institution.

Its position in the front rank of technical societies has been recognised in many other ways. The Institution of Naval Architects is one of the five societies represented on the Engineering Standards Committee: the chairmanship of a most important committee (that of steel sections) has been held by one of our representatives, Mr. Archibald Denny. The Institution is also represented on the Executive Committee of the National Physical Laboratory, as well as the Special Committee appointed to supervise the operations of the National Experimental Tank, which has been added to the equipment of the laboratory by the splendid generosity of our Vice-President, Mr. Yarrow. The official opening of that tank to-morrow is one of the most important and interesting events in our programme, and will constitute a fitting memorial of the Jubilee. The provision of a maintenance fund for that tank is another public duty which has been undertaken by the members of this Institution, and there is no doubt but that it will be fulfilled.

The Institution is represented on the Courts of the Universities of Liverpool, Bristol, and Sheffield, and upon the Governing Body of the Imperial College of Science and Technology in London. Members of the Institution are serving at the present time on the Special Committee appointed to consider reports on the establishment of a Science Museum in London. These are but examples of the public services which have been rendered since the Institution was founded, and which have grown in importance with its growth.

Perhaps the strongest evidence of the value attached to the national work done by the Institution may be found in the fact that for a very long period the Admiralty has made an annual grant in aid of that work This grant was first made when the financial condition of the Institution was a cause for anxiety to the Council, and aid was then of greater relative value than it has been in later years, when financial difficulties have disappeared. As a recognition by the Government of the public duties performed by the Institution the continuance of the grant is highly esteemed.

The Transactions of the Institution.

Every one will agree that important as other departments of its work have been and still are, the most important is represented by the fifty-two volumes of its Transactions.

These volumes contain a detailed record of progress in the science and practice of shipbuilding and marine engineering during the period they cover. Reference has already been made to the paper in which Dr. Woolley ably summarised the condition of the mathematical theory of naval architecture in 1860. Another stock-taking of scientific knowledge was attempted by Sir Edward Reed when the International Congress of 1897 was held in London, and his paper showed that, in many branches of naval architecture, considerable advances had taken place since 1860; especially in those branches relating to the stability and oscillations of ships, fluid resistance, and propulsion of ships, the mechanical theory of propellers, and investigations of the structural strength of ships. Since 1897 progress has continued, and is still continuing. The later volumes contain full records of the most recent additions to the vast treasury of information gathered in preceding Transactions, and they are in no sense inferior to their predecessors. At the outset Sir Edward Reed remarked that one of the most important factors in the success of the Institution would be the contribution of original papers in sufficient numbers. Fears on that head were speedily dispelled; from the first the supply of papers of excellent quality were in excess of requirements. In later years—even with an increasing demand for contributions of a similar kind from local societies—the supply to the parent Institution has been in excess of what could be read and adequately discussed within the limits of time available.

The Institution, in fact, offers unrivalled attractions for the authors of papers, and especially for the originators of new ideas or experimentalists in new directions; because of its larger membership, cosmopolitan character, and high reputation as the best means of making known to the shipping world new methods and discoveries in the domain of naval architecture and marine engineering Our Transactions contain numerous original communications by distinguished men, whose contributions mark epochs in the history of ship design and construction; and who have chosen our Institution as the most suitable place for publication of successive steps in invention and research. Theory and practice both find adequate representation; and illuminating discussions, as well as independent and differing views on particular subjects expressed by high authorities, add greatly to the value of the record.

The first volume of the Transactions struck a high note which has been since well maintained. In addition to Dr. Woolley's paper on the theory of naval architecture, this volume contained contributions from Sir George Airy on compass correction in iron ships, from Scott Russell on the wave-line principle of ship construction, and from Mr. Barnes on experiments to determine the height of the centre of gravity of ships. Iron shipbuilding was discussed by high authorities like Sir William Fairbairn and Grantham. John White, of Cowes, described the diagonal system of wood shipbuilding, with which most remarkable results were obtained in the combination of lightness and strength. Sir Nathaniel Barnaby wrote on mechanical invention in its relation to the improvement of naval architecture. Mr. Moorsom dealt with tonnage legislation of ships. Mr. Robert Murray described means and appliances for economising fuel in steamships. Mr. Lennox read a paper on chain cables. This was an excellent start, representing all sides of the work which the Institution was founded to perform.

In Volume II. of the Transactions, prolonged discussions on ironclad ships were recorded, these discussions continued over several years, and had immense public interest and value at a critical time. Mr. William Froude contributed a paper on the rolling of ships, which introduced a new view of the causes influencing the behaviour of ships at sea, and gave clearer guidance to naval architects in their treatment of the conflicting qualities of stiffness and steadiness in new designs for ships. Papers on the methods of making the calculations for the stability of ships were also read. That by Mr. Barnes formed the first of the long series of such investigations contained in subsequent Transactions. Next year a feature was developed which has since become common in our proceedings. A paper like that by Mr. Froude on the rolling of ships could not possibly be mastered when it was read or immediately discussed: it required careful study before the real meaning and value could be understood, or doubtful points and limitations discovered. In 1862, therefore, as was natural, a number of papers appeared dealing with this subject from different points of view, and, as a result, knowledge was advanced. Later on Professor Rankine began a series of contributions which were of the greatest value in connection with the oscillations of ships; and still later came experimental and analytical investigations by Mr. William Froude, Mr. R. E. Froude, and others, with the final result that the fullest discussion extant of this branch of naval architecture is to be found in our Transactions.

The same claim may be made for the treatment in these volumes of the important subject of stability, both on the theoretical and the practical sides, and for all classes of ships. A great mass of authentic data has been accumulated; the effects of variations in form, type, and lading investigated, methods of calculation described, and attention drawn to the valuable help obtainable by the use of integrating machines, in the production of which Dr. Amsler took the lead when the need for them was made clear by discussions in this Institution.

In the Transactions also may be found the epoch-making communications of William Froude, relating to his system of experiments on models of ships and propellers; contributions from Wm. Froude, Rankine, R. E. Froude, Cotterill, Greenhill, and other authorities on the mathematical theory of propellers, and the causes chiefly influencing their efficiency; records of experimental research on water-resistance to the motions of ships and speed trial data for actual ships.

Questions of the greatest importance to the mercantile marine, such as rules for classification, legislation for load-lines, tonnage measurements, watertight subdivision, corrosion and fouling, stowage of cargoes, loading and discharging appliances, anchors and cables, refrigerating apparatus, steering gears, docks, harbours and ports, fire protection, masts and spars, boat lowering, and endless other items have all been made the subject of papers and discussions.

If one desires to obtain accurate information as to improvement in shipbuilding materials, the substitution of iron for wood, the construction of composite ships, the introduction of mild steel, the use of stronger qualities of steel, the advantages or disadvantages of various kinds of material, the Transactions offer the greatest facilities.

Similarly, one turns to them for information in regard to systems of construction, structural arrangements, methods of riveting and combining parts of the structures of ships; and one never turns in vain. Methods of approximating to the principal stresses which may come upon various parts of the structures of ships, and deciding on the upper limits of stress which experience shows may be accepted in practice, as well as the determination of local stresses, and of the best methods of meeting them, are also to be found in these volumes.

Scientific analysis and practical experience are herein associated, and always with advantageous results. All classes of vessels receive consideration, ranging from the lifeboat up to the great ocean-going passenger steamship or the monster battleship; ice-breakers, railway ferry steamers, telegraph-laying steamers, steam and sailing yachts, torpedo vessels, submarines, and others; all have come under review, or been made the subject of discussion. Nothing that floats is too small or too great to receive attention from the Institution and a place in the Transactions.

In the Transactions are also to be traced in detail, authentic records of the remarkable progress made during the last half-century in marine engineering, increase in steam pressure, improvements in steam generation in propelling and auxiliary machinery, in fuel economy, in systems of propulsion and propellers. The stories of the development of the reciprocating engine, the introduction and disuse of water-jet propellers, and the triumph of the steam-turbine, are all told as they happened. Recently the application of the internal-combustion engine to ship propulsion has been debated, and its history is being written. Liquid fuel for the use of steamships was discussed in this Institution forty years ago; and, now that it is coming into more general use, the economic results are being investigated by competent authorities. The relative merits of cylindrical and water-tube boilers, of different types of superheaters and condensers, of various systems for the transmission of power, come under review. No one can peruse these pages and fail to be impressed with the remarkable growth of scientific method, accurate observation, systematic research, and thorough analysis; as applied to the design, construction, and performances of ships, marine engines, and boilers. Related problems such as the vibration of steamships, the balancing of engines, the influence of rate of revolution, and numbers or positions of propellers upon vibration—have all received attention. The aggregate result of these advances in knowledge are to be seen in the increase of speed, the practical supersession of the sailing ship by the steamship, the cheapening of sea transport, and the greater regularity and comfort of sea travel, with all the consequent benefits to humanity at large.

This brief and imperfect review of the outstanding features in our Transactions cannot be concluded without a reference to the intimate connection which has existed between the proceedings of the Institution and the contemporaneous development of the Royal Navy. Here from the commencement have been held debates on warship construction far more valuable than any discussions in Parliament could possibly be on such highly technical subjects. Here naval officers and naval architects have met and conferred or disputed. From the very outset the Institution was chosen as the place whereat the constructive policy of the Admiralty for the time being should be explained and discussed. All through the periods of office of Sir Edward Reed, Sir Nathaniel Barnaby, and myself, as the responsible designers of ships of the Royal Navy, this policy was continued. It was at our meetings that the relative merits of broadside and turret armaments were championed by Reed and Cowper Coles, and descriptions have been given by men responsible for the designs of new types while they were building. Here the controversies of the past were centred, and to a large extent were settled, in all probability to the great advantage of the nation. These controversies need not be revived, but they can still be studied in the Transactions, and the student finds that in warship design, as elsewhere, history often repeats itself. In these pages can be found records of the long battle between ordnance and armour, of the great improvements made in each, and the consequential effects on designs. In recent years all this has been changed, and, as many of us think, unfortunately changed, when regard is had to the undoubted benefits which have flowed from open discussion in the past. For many years now the Institution has had no official communications made to it, such as were formerly the rule, respecting the designs for new British warships. It is hoped that before long there may be a reversion to earlier and well-proven practice. In the past some things have always been left unsaid in papers contributed by officials. It is not suggested that in future there should be disclosures of information that would be indiscreet or improper any more than there has been in the past. As one familiar with the events of the last forty-five years in our proceedings, I cannot recall one occasion where the public interests have suffered in consequence of the papers read and discussed in which warship design and construction formed the subject.

Looking back upon work which has been done by the Institution, it may be claimed that the intentions of its promoters, on the whole have been well fulfilled; in some respects they have been surpassed. The meetings of the Institution have afforded exceptional opportunities for the discussion of questions affecting the science and practice of naval architecture and marine engineering; the construction of warships and of merchant ships; the shipbuilding policy of Great Britain; the safety of life and property at sea; the introduction of new materials of construction and structural arrangements; the development of experimental methods of research; the introduction of new methods of ship calculations and design; and the discussion of new inventions of various kinds. Before the Institution was founded, naval science had no home in England; its treasures lay scattered far and wide in the form of memoirs and papers contained in the Proceedings of the Royal Society or in other publications. Everything worthy of preservation now naturally finds its way to the Transactions, and through them to naval architects, marine engineers, and others interested in these subjects throughout the world. All movements sensibly affecting shipping now leave their record in the papers and discussions; from this point of view the Transactions have already attained and will maintain a high historical value. Every great movement may be said to have been chronicled for fifty years, and the history of the progress of the theory of naval architecture is also to be found therein.

Sanguine as were the founders, it seems unlikely that any of them could have anticipated such a growth in numbers, standing, and recognised usefulness as has taken place. Most of those to whose courage and devotion the establishment of the Institution was due have passed away; others, who have done their best to promote its interest and further its operations for many years, will soon come to the end of an active participation in its affairs. It may, however, be asserted confidently that the Institution we all love so well will live and flourish, because it has become a centre of association and friendly help for all who are interested in ships—the home of naval architects and marine engineers of all maritime countries, as well as of shipowners and seamen.

Growth of Bristol—In 1897 the rateable value of Bristol was 1,153,311*l.*; in 1910 the total had grown to 1,845,161*l.*

SHIPPING ON THE GREAT LAKES.*

By FRANK E. KIRBY, Vice-President Soc. N.A. and M.E., and A. P. RANKIN, Member.

THE object of this paper is to describe and illustrate, without touching on the technical side of the subject, the water-borne commerce of the Great Lakes of America. The writers offer it apologetically, realising the futility of attempting to cover in detail so large a subject in a paper of necessarily restricted length, but they trust that by indicating some of the outstanding facts in this development their efforts may not be without some interest.

In beginning it may not be out of place to give briefly a *résumé* of the physical features regarding the Great Lakes, together with their connecting navigable channels and principal ports. Also, although the object will be to avoid statistics as far as possible, it will be necessary to submit sufficient of these for an intelligent realisation of the volume of the trade, together with its rapid increase. Consisting of a series of inland seas, known as Lakes Superior, Michigan, Huron, Erie, and Ontario, reaching east and west 1000 miles, and half that distance north and south, with a water surface of over 90,000 square miles and a drainage basin of 275,000 square miles, connected throughout by navigable channels and discharging through the St. Lawrence River into the Atlantic Ocean, they may be justly considered, from their magnitude, the great area of the region drained by them, and their beneficial effect on the climate, one of the most important physical features of the North American Continent.

Lake Superior, the most westerly of the group, is 602 ft. above mean sea level, while Lake Ontario on the east is elevated only 247 ft. Between Lakes Superior and Erie, however, the fall is somewhat less than 30 ft., so that almost the entire descent is below Lake Erie, or in the Niagara and St. Lawrence Rivers. The difference in level between Lakes Superior and Huron is about 21ft., the natural channel being the St. Mary's River. The St. Mary's Rapids have a drop of 18 ft. in about three-fourths of a mile, and navigation at this point is accomplished by means of the Sault Ste. Marie (or commonly the "Soo") canals, of which there are two, one in United States and one in Canadian territory, the former having two locks, side by side, while the latter has a single lock. In all cases the total lift of 18 ft. is overcome in one lock. The older of the United States locks, known as the "Weitzel," was built in 1870-81, and is 515 ft long, 80 ft. wide in the chamber, narrowing to 60 ft. at the gates with 17 ft. of water over the sills.

The latest, or "Poe" lock was built in 1887-96, and is 800 ft. long, 100 ft. wide, with 22 ft. of water over the sills. The Canadian lock is 900 ft. long, 60 ft. wide throughout, and was built in 1888-95. Either of these locks can be filled or emptied in seven or eight minutes, and the gates opened or closed in two minutes. A third United States lock is under construction at the present time, on completion of which it is proposed to rebuild and deepen the "Poe" lock, and a fourth lock is contemplated. Since 1881 no tolls have been levied, both canals being free for use by ships of all nations. The average time in making a lockage is about 30 minutes, but generally two, and frequently as many as five, boats are put through at once.

The navigable channel through the St. Mary's River has been improved, by dredging and cutting, until the available depth is in the neighbourhood of 20 ft.

Lakes Michigan and Huron connect through the Straits of Mackinac and have a common level. The connection between Lake Huron and Lake Erie is through the St. Clair River, Lake St. Clair, and the Detroit River, the difference of levels, 8 ft. in about 90 miles, causing an average current of 1½ miles per hour, increasing to 2½ at the narrow channels. By an amount of work and at an expense difficult to realise these channels have been deepened and improved, until 20 ft. of water is available throughout at normal lake levels.

The Welland Canal, which is built entirely in Canadian territory, connects Lake Erie with Lake Ontario, overcoming the Rapids and Falls of Niagara. The canal is 26¾ miles long, the total lift being 326¾ ft., accomplished in 25 locks, each 270 ft. long, 45 ft. wide, with 14 ft. of water available. It is the intention, however, to confine this paper to the commerce of the Great Lakes above Niagara Falls, as the comparatively small dimensions of the Welland and lower canal locks make Buffalo the eastern terminal of the great bulk of the lake traffic, which is handled in ships of much greater dimensions. Between Lake Ontario and Montreal, however, there are six canals, and 21 lockages are necessary, the dimensions of lock and depth of water given for the Welland Canal being available throughout.

The sailing distance from Buffalo, at the eastern extremity of Lake Erie, to Duluth, the western limit of Lake Superior, is 980 miles, and from Buffalo to Chicago, at the southern end of Lake Michigan, 885 miles, while from the lower end of Lake Ontario to Duluth is 1175 miles.

Navigation on the Great Lakes opens about the middle of April and closes early in December, leaving a navigation season of eight months. During the four winter months the rivers and harbours are ice-bound, and navigation entirely ceases, except in the case of car and other ferries.

The international boundary line divides Lakes Ontario, Erie, Huron, and Superior, passing midway through the connecting channels, and leaving Lake Michigan entirely in United States territory.

It is not the intention to attempt anything like a historical description of the early navigation and development of the commerce on the Great Lakes, but generally to describe it as it now exists, referring, of necessity, to the small beginnings by way of contrast, and to illustrate the rapid advance that has taken place.

The chief reason for the growth of this commerce is the proximity of great natural resources to the districts tributary to the lakes, the bulkiness of the products making water transportation specially valuable. This condition naturally existing, what had to be artificially provided was the means of cheap transportation by water, which in turn necessitated deep waterways, so that large ships could be utilised, special types of ships to handle the different kinds of cargoes, and adequate facilities for handling the same. The gradual advance along these lines constitutes the real story of the growth of the commerce of the Great Lakes, the deepened and improved waterways always in the van, the ships of increased dimensions following closely, and the cargo handling apparatus keeping pace with their structural arrangements, and often, indeed, causing radical changes to be made in their design.

Probably the simplest way to a realisation of the volume of this commerce is a study of the statistics covering the tonnage passing given points in the navigable channels. That through the Sault Ste. Marie canals represents the Lake Superior traffic, and accurate records are kept at this point. This represents about two-thirds of the Detroit River tonnage, the remaining third being mostly traffic to and from Lake Michigan ports. The following tables show the amount of tonnage passing these points during the navigation season of 1910 :—

East and West-Bound Commerce Passing both American and Canadian Canals at Sault Ste. Marie, Michigan, and Ontario, for the Season of 1910.

East Bound.

Articles.	U.S. Canal.	Canadian Canal.	Total.	Total Sh. Tons.
Copper, short tons	121,438	26,632	148,070	148,070

Summary.

Vessel passages, number	12,927	7,972	20,899	
Registered tonnage, net	26,506,986	23,349,137	49,856,123	
Freight—				
East-bound, short tons	15,602,673	31,351,036	47,133,709	
West-bound, short tons	10,324,988	4,904,521	15,229,509	
Total freight, short tons	25,927,661	36,435,557	62,363,218	

The volume and increase of traffic in the Detroit River is illustrated by the table given below, covering the years 1902 to 1910 :—

Year.	No. of Passages.	Net Registered Tons.	Freight Tons. Estimated.	Estimated Value.
				dols.
1902	33,000	39,328,659	44,260,506	440,834,640
1903	33,113	37,453,796	46,817,245	471,917,830
1904	29,472	33,049,984	42,792,326	453,598,656
1905	35,599	45,912,622	55,508,360	522,888,751
1906	35,128	50,673,897	63,808,571	662,971,053
1907	34,149	53,959,769	71,226,895	697,311,302
1908	27,883	40,628,350	54,086,750	614,425,480
1909	32,296	54,668,846	67,789,369	732,803,079
1910	33,638	58,821,282	73,526,602	771,294,055

On the lakes, iron ore is reckoned in tons of 2240 lb., commonly known as the "gross" ton, while for coal and other merchandise the short or "net" ton of 2000 lb. is used. To simplify the tables all weights are given as short tons, while elsewhere, where necessary, the tons will be qualified by the terms above. This, in 1910, averaged about 225 tons passing this point for every minute of the navigation season.

An examination of the table of statistics covering tonnage passing through the "Soo" locks will show that the bulk of the cargoes carried consisted of a comparatively few articles. Thus, of the 62,363,218 tons passing east and west, 41,603,634, or over 66 per cent. of the whole, is iron ore. Coal contributes 13,513,727 tons, or nearly 22 per cent., grain and flour accounts for 3,345,512 tons, or 5½ per cent., these three articles making over 93 per cent. of the total, and it thus becomes an easier problem to specialise the ships, docks, and cargo-handling apparatus. The ships engaged in this great commerce may be roughly, but with sufficient exactness, divided into four classes as follows :—

1. Coarse or bulk freighters, including all steamers engaged in carrying iron ore, coal, or grain in bulk.

2. "Package freighters," covering steamers carrying general merchandise in holds and on main deck, handled generally through side gangways.

3. Passenger steamers.

4. Car ferries, used in the transportation of railroad cars across the rivers and lakes.

Bulk Freighters.—The development of the freighter on the lakes is so interwoven in its history with the improvement of the waterways and the perfecting of the cargo-handling apparatus, that it would be impossible to follow one without tracing also the simultaneous advance of the others. A somewhat superficial review, however, touching only on the most important steps, must suffice to lead up to the bulk freighter of the Great Lakes as she exists to-day. This type of ship is engaged exclusively in the carrying of iron ore, coal, and grain. The ore trade is entirely down the lakes, or east bound, the principal shipping ports being Duluth, Superior, Two Harbors, Ashland, and Marquette on Lake Superior, and Escanaba on Lake Michigan. Of the 42,620,201 tons carried during the navigation season of 1910, 34,012,897 tons were received at Lake Erie ports, the balance being delivered to those of Lake Michigan.

The grain traffic, also east bound, amounted in 1910 to 245,171,763 bushels, the principal shipping ports for United States grain being Duluth, Superior, Chicago, and Milwaukee, the receiving ports being Erie and Buffalo, from where it is shipped by the Erie Canal railroads for distribution and export. Port Arthur and Fort William, Ontario, are the storage and shipping points for the grain from the Canadian North-West, most of which is carried to the seaboard for export between September and December. The larger steamers transfer to the railways at Georgian Bay ports, while those of Welland Canal dimensions cover the entire route from the head of the lakes to Montreal.

The coal trade, being all west bound, forms a convenient return cargo for steamers which are not exclusively engaged in the ore trade. It ranks second in volume, and during the navigation season of 1910, 18,406,469 tons of bituminous and 4,170,813 tons of anthracite coal were shipped west from Lake Erie ports.

Freight rates between Lake Erie and Lake Superior ports during 1910 were as follows :—

Coal	31 cents per ton.
Grain	1⅓ cents per bushel.
Iron ore	70 cents per ton.
General merchandise	2.00 dols. per ton.

From the ore rate above 15 cents per ton must be deducted for unloading charges, which are borne by the vessel's owner.

The iron-ore trade is, of course, the most important, and the relation of the lakes to the mining and transportation of the ore has done more to establish the position of the United States in the iron and steel trade of the world than any other fact. Three-quarters of the ore used in the furnaces of the United States comes from the Lake Superior region, a thousand miles removed from the available coke and limestone supply, and but for the lake transportation it would be impossible to economically assemble them, the traffic, at rates profitable to the steamers, offering no attraction to the railways; in fact, without this great water route the Lake Superior ore deposits could never have been developed.

Iron ore was first discovered in the Lake Superior district in 1844, about 14 miles from what is now Marquette, and, at first, attempts were made to manufacture iron in the locality of the deposits, and several forges were established in the years 1848-50, but financially the results proved disastrous. The difficulties of transportation to the lake, the long trip to the mills in Pennsylvania, made the cost of the blooms so high that it was impossible for the industry to continue. In 1850, 10 tons of iron ore were sent to New Castle, Pennsylvania, for experimental purposes, but it was not until 1853 that the idea of manufacturing iron in the Lake Superior district was abandoned, and definite steps taken toward shipping the ore to the lower lakes.

In the early shipments the ore was laboriously hauled to the lake, wheeled on board small sailing vessels, and at the "Soo" had to be unloaded, carried over the portage of about a mile, and below St. Mary's Falls was again loaded upon vessels, and so carried to the Lower Lakes. Meanwhile, a canal around the rapids at Sault Ste. Marie was under construction, work being commenced in 1852, and on June 18, 1855, the canal was opened for traffic. The steamer North Star, passing up through the canal on the 20th, was the first to reach Marquette, and the brig Columbia carried the first ore cargo, consisting of 132 tons, through the canal on August 17, 1855, and in all 1,447 tons were shipped that year. The first ship canal at Sault Ste. Marie was 5,700 ft. long, 100 ft. wide at the water surface, 64 ft. wide at the bottom, and the depth of water was 13 ft. The locks were two in number, 350 ft. long, 70 ft. wide, with 11½ ft. of water over the sills, and each had a lift of 9 ft.

In 1857 the first steam railroad from the mines to Marquette was finished. It was not until 1862 that any of the mining companies found themselves on a paying basis, but meantime they had joined together in building, at Marquette, a wooden dock with elevated pockets on trestle work, to facilitate the loading of the ore. Primitive as the structure was, it represented in principle the great loading docks of to-day, embodying the universal method of loading through spouts from elevated pockets, filled by cars from above.

For the first few years almost all the ore shipments were made on small sailing vessels, on which, owing to their construction, with the ordinary hatchways, this method of loading could be used. The few steamers of those days all carried passengers, and were in no way adapted for the transportation of ore. As the channels

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 6, 1911.

were not lighted navigation through them ceased at nightfall, and the custom was for the schooners to be towed through the rivers, numbers of tugs finding steady and profitable employment in this connection. In the sixties this was the general method of ore transportation on the lakes, and in 1860 115,401 tons of iron ore represented the year's business in that commodity.

At this time the method of unloading ore at the Lake Erie ports was an exceedingly slow and laborious one. The work was usually done by contract, the means employed to elevate the cargo from the hold being tubs, operated by blocks and tackle with horses as the motive power, and wheelbarrows then served to convey it ashore. To unload a 400-ton cargo in two days was accounted excellent work. In 1867 small portable engines were substituted for the horses, and at once the unloading time was cut in two. Up to this time ore was not the most important trade on the lakes; grain, then, and for many subsequent years, holding that position. In 1866 grain receipts in Buffalo were 1,500,000 tons, while the total ore delivered at all Lake Erie ports represented only 278,796 tons. For some years as the traffic increased the system was adopted of towing sailing vessels, five and six in line, the entire distance from the loading docks on Lake Superior to Lake Erie. The year 1869 marks an important change in the business of ore carrying in the introduction of the steamer and consort. In that year the steamer R. J. Hackett was built at Cleveland, Ohio, being, as the term is now generally understood, the first bulk freighter on the Great Lakes. She was of wood, 211 ft. long, and 33 ft. beam, the propelling machinery being placed aft. Her hold was continuous, and her hatches spaced 24 ft. centres, influenced, no doubt, by the design of the early loading docks on Lake Superior. She had a carrying capacity of about 1,200 tons, the draught being, of course, fixed by the 11½ ft. of water at the "Soo" locks. The following year the Forest City, of approximately the same dimensions, was built as a consort to the Hackett, and the two vessels were operated together. Although intended to be always in tow of the steamer, she was rigged with sufficient canvas to care for herself in case of being dropped through stress of weather. This method of transporting ore by means of steamers and consorts became rapidly popular, and continued as the prevailing practice for almost twenty years thereafter.

In 1874 the steamer V. H. Ketchum was launched at Marine City, Mich., and being 20 ft. longer than anything afloat on the lakes at that time was considered a monster. She was of wood, 233 ft. long, 41 ft. beam, and 24 ft. deep.

About this time the demand became general and insistent for a deeper channel throughout the Lake System. Draughts of 13 ft. and over were possible at some of the principal lake ports, yet the draught of ore-laden vessels was regulated by the depth of water at the "Soo" locks, viz., 11½ ft. A 16-ft. channel throughout was decided upon, the first step toward which being an increase in the depth of the St. Mary's Fall's Canal from 12 ft. to 16 ft., and the construction of a new lock 515 ft. long and 80 ft. wide, to provide for the whole 18 ft. difference of level in one lift. This new lock, the "Weitzel," was completed in 1881, but it was 1884 before the 16-ft. channel was available throughout. In the meantime a large fleet of vessels had been built of dimensions to utilise to best advantage the increased facilities, and the principal ports had been deepened to suit. At this time the growth of the ore-carrying trade had been notable, shipments having increased from 300,000 tons in 1866 to 2,300,000 in 1884. In 1882 a departure from the use of wood in shipbuilding was made by the construction at Cleveland, Ohio, of the steamer Onoko, the first iron bulk freighter built on the lakes, and for a time the largest dead-weight carrier, her dimensions being 287 ft. in length, with a beam of 38 ft. With the development along other lines the ore-loading docks at the Lake Superior ports had been gradually and consistently enlarged to keep pace with the requirements. The construction of these docks has always influenced the arrangements of the ships in one way. The loading spouts were originally placed at 12 ft. centres, and on account of this the early boats were built with their hatches spaced 24 ft. centres in order that each alternate spout could be used without shifting. The early docks were invariably of timber, with the base of the pockets only 20 ft. above water, this giving sufficient incline for the flow of the ore. Concrete and steel, however, enter largely into the construction of the modern ore-loading dock, and Fig. 1, Plate X., shows the Duluth and Iron Range Company's dock, No. 6, at Two Harbors, Minn. This dock is 40 ft. from waterline to bottom of pockets, and 73 ft. high to railroad track, and has storage capacity for 43,246 tons. The steamer shown under the loading spouts is 569 ft. long over all, and on October 10, 1909, was loaded with 10,111 tons of ore in 39 minutes.

In unloading, however, no material advance had been made, the portable engine, buckets, and wheelbarrows prevailing as late as 1880. The first real improvement was introduced at Cleveland by the building, in 1882, of a cable-way machine designed by Alex. E. Brown, which marks the beginning of the speedy development of the material-handling machinery on the lakes. It consisted of a number of cables, each supported on two fixed piers, one at the dock face and the other some 300 ft. back. On each cable ran a one-ton ore bucket, controlled in its movements from a central station. The buckets were filled by hand in the hold, the machine lifting out, depositing the ore on the storage pile or directly into cars, and returning the empty bucket to the hold without further hand labour. Although an infinite improvement over the old method, the limitations of a machine with fixed piers was soon realised, in that it could cover only a limited storage pile, and it soon gave place to the type carrying a rigid bridge structure instead of the cable, the piers being mounted on wheels and movable along the length of the dock. This type was brought to great perfection by the Brown Hoisting Machinery Company of Cleveland, and became the almost universal standard, their capacity being largely limited by the speed of filling the buckets. Fig. 2, Plate X., shows the highest development of this class of machine, superseded now by the "grab-bucket" type.

Steel was first introduced in the construction of bulk freighters on the lakes in the building of the Spokane in 1886, and this speedily became the only material used. When in 1884 the 16-ft. channel became available, a great many steamers of 1500 to 1900 tons net register, with a carrying capacity of about double that amount were in use. In 1888 iron ore became the leading article of commerce on the lakes, a position which it has retained uninterruptedly since, and from that time the vessels built for that trade were greater in number and larger in tonnage than those for any other. In constructive features they were yet practically the same as the Hackett and Forest City. Steel had been substituted for wood, the double bottom had been added, but the internal arrangements remained substantially the same.

The demand for deeper waterways on the lakes has been unceasing, and the 16-ft. channel was no more than completed when it was realised that it was totally inadequate to the demands of the commerce, and measures were taken towards increasing it. The improvements included the further deepening of the St. Mary's Canal to 25 ft. and the building of a new lock, 800 ft. long and 100 ft. wide, with 22 ft. of water over the sills. This, the present "Poe" lock, was built on the site occupied by the first lock, and was opened for traffic in 1896. Simultaneously, the work on the Canadian Canal and lock had been carried on, it being completed the year previous. The channels through the connecting rivers were also improved by deepening, straightening, and making safer for night navigation, and the effect of this new 20-ft. channel was immediately felt in increased ship dimensions. In 1896 more than half the tonnage in bulk freighters built exceeded 2000 tons net register, while six years previously not a single vessel of this tonnage was in service.

The first of the 400 ft. class, built in 1895, marked a departure from ordinary construction in the wide spacing of her main deck beams. This was the steamer Victory, 400 ft. long over all, 48 ft. beam, and 28 ft. deep. Her carrying capacity was 5200 tons on 18 ft. draught, and at that time she represented the highest development of the bulk freighter. It is evident that with the class of bulk cargoes carried in these ships intermediate decks are unnecessary, the cargo being carried entirely on the "tank top" or inner bottom. Up to the time of the introduction of the hopper-type ship the so-called main-deck beams, on which, however, no deck was laid, and hold stanchions, were invariably installed for structural reasons. On the Victory the arrangement was simplified by spacing these beams 8 ft. apart. In 1897 steamers of 475 ft. in length appeared, and about this time were built the last of the "consorts," owners realising that the highest economy in operation was reached by the single steamer of large carrying capacity and comparatively low power.

In 1899 there was installed at Conneaut, Ohio, a new type of ore-unloading machine, the "Hulett," operating a self-filling or "grab" bucket, which marked a point of radical change, both in the design of unloading machinery and in the internal arrangements of the ships. Up to this time the ore had been handled in one-ton buckets, the size found most satisfactory for hand filling, but with the new mechanical buckets the capacity seemed to be limited only by the clear space available in the hold. Since the introduction of the grab bucket two types of machines have been developed, one in which the bucket is suspended by the operating ropes, and the other in which the bucket is mounted on the lower end of a vertical rotating leg operated by an oscillating beam.

Fig. 3, Plate XI., represents one of the former type built by the Brown Hoisting Machinery Company, of Cleveland, Ohio, this machine being arranged to deliver directly into cars. On July 21, 1910, a machine of this type, using six 5-ton grab buckets, unloaded 9681 gross tons of ore from the steamer Matthew Andrews in 5 hours and 58 minutes, or at the rate of 353.2 tons per hour for each bucket.

Fig. 4, Plate XI., illustrates a "Hulett" type machine, built by the Wellman-Seaver-Morgan Company, of Cleveland, Ohio. Operating four 15-ton grab buckets, this machine unloaded from the steamer Thomas F. Cole, on August 5, 1910, 11,131 gross tons of ore in 4 hours and 30 minutes, or at the rate of 618 tons per hour per bucket.

In 1900 the first "500-ft." steamers appeared, but during the two or three years following the dimensions dropped back slightly. In 1902 the steamer James H. Hoyt was built, with her nineteen hatches spaced 12 ft. centres, making it possible to use loading spouts in all hatches simultaneously, and allowing greater freedom in the hold. This created new records for both loading and unloading.

Two years later, in 1904, was witnessed the most radical change ever made in the construction of lake freighters. A steamer was built 60 ft. longer than any other vessel on the lakes, and differing materially in construction from the existing type. This steamer was the Augustus B. Wolvin, 560 ft. long, 56 ft. beam, and 32 ft. deep. She had 33 hatches, spaced 12 ft. centres, and her hold construction was novel, beams and stanchions being omitted entirely and compensating strength secured by heavy plate arch-girders under the spar deck, between hatches. Instead of the usual practice of running the "tank top" or inner bottom out to the ship side, it was carried up to the edge of the main-deck stringer, the sloping sides forming the hold into a long, continuous hopper, as shown on Fig. 5, Plate XI. The space thus formed on each side, between the hopper sides and skin of ship, added materially to the capacity for water ballast, the cargo was concentrated within the reach of the unloading machines, and all obstructions to the working of them removed from the hold. The success of the type was instantaneous, and since that time every bulk freighter on the lakes has been built on some modification of this design.

Fig. 6, Plate XI., shows the type of hopper hold now generally adopted, and illustrates how the grab buckets may be turned, after passing through the hatches, to clean up the ore close to the vertical sides of the hopper.

Considerable work has been done on the older-type steamers in the re-arrangement of the main-deck beams and grouping of the stanchions, and, latterly, vessels of the earlier type have been entirely changed to the arch or girder construction, for the fact is obvious that for the economical handling of ore by present-day unloading machinery the hold must be entirely free.

The bulk freighter of the Great Lakes to-day, while not a thing of beauty from the marine architect's point of view, is, nevertheless, a most efficient, economical, and capacious carrying machine, excellently suited to the requirements of the business she was intended for and is engaged in. Ordinary practice and accepted formulæ have affected her design but little. Extraordinary conditions had to be met, and the result has been the evolution of a type of ship peculiar to the conditions of the trade in which she was to operate. She represents no compromise design, but is planned with a single purpose in view, no thought being given to the possibility of her ever engaging in business of any other nature. Under present conditions she is still unhampered as to length, and two steamers 617 ft. long are at present under construction. As, however, a width of 60 ft. or over prevents the use of all the "Soo" locks except the "Poe," the possibility of serious delay through the derangement of this lock has to some extent governed the beam of the ships, and 58 ft. has been generally adopted as the maximum up to date, although several steamers of 60 ft. beam are in use. The great length, in comparison to the limited depth available, makes the question of longitudinal strength an all-important one, while the extreme athwartship width of the hatches complicates the problem somewhat. The speed of loading ore precludes the possibility of taking the steamer under the loading spouts with any considerable amount of water ballast, as it is impracticable to discharge it as fast as the ore is run in. Therefore, to get the necessary slope of the spouts to insure the proper running of the ore, with the ship in a light condition, the hatches are made about two-thirds the beam of the ship in width. The full lines, square middle body, bluff bow, and practically flat bottom, the extreme forward position of the navigating bridge, the long sweep of deck, clear of spars and pierced by hatches from end to end, the hopper hold, free from cross-beams and stanchions, and spanned by the deep spar-deck girders, the arrangement of the steel hatch covers, and method of removing and replacing them, the absence on board of all cargo-handling machinery, the large capacity for water ballast, the compactness, simplicity, and economy of the propelling machinery, together with its comparatively low power, the labour-saving devices, the consequent small crew required, and the superior accommodation provided for them, together with the almost entire absence of wood in the construction, are a few of the striking characteristics of the bulk freighter of to-day.

The following are the principal dimensions of one of the "600-footers," common enough now on the lakes to constitute her a typical example of the latest practice:—

Length over all, feet	600
Length between perpendiculars, feet	580
Beam moulded, feet	58
Depth moulded, feet	32
Carrying capacity in gross tons at 19 ft. draught	10,400
Displacement in gross tons at 19 ft. draught	15,350
Block coefficient, per cent.	86
Length of cargo-hold, feet	440
Width of cargo-hold at bottom, feet	36
Capacity for water ballast, gross tons	8,000
Number of hatches	36
Clear opening of hatches, feet	36 by 9
Number of crew	25
Type of propelling-engine: Triple-expansion jet-condensing.	
Diameter of cylinders and stroke, 25 in., 39 in., and 65 in. by 42 in.	
Revolutions per minute	85
Indicated horse-power	2,000
Number of boilers	2
Type and size in feet: Cylindrical, 16 ft. by 11½ ft.	
Working pressure, lbs.	180
Loaded speed, miles	11½

Fig. 7, Plate XII., shows, as an exception to the general rule, a freighter carrying her own unloading machinery. Two of this class are in use on the lakes carrying crushed limestone, and by an arrangement of hopper hold, travelling scrapers, and elevators, the cargo is delivered on the dock entirely without hand labour.

Package Freighters.—General merchandise, outside of shipments made in bulk, and known as "package freight," forms a very considerable trade on the Great Lakes, amounting annually to over 7,000,000 tons, which is handled almost entirely in steamers of greater speed than the bulk freighters, built expressly for the traffic, and owned and operated by, and in connection with, the great railway systems. Single-screw vessels of the

double-deck type are used, and, although many of the earlier steamers had their machinery amidships, the later types, in common with the prevailing practice on lake screw steamers, have their engines and boilers aft. They are divided into two classes, those carrying freight only, in which type the boilers are frequently placed on the main deck, in order to increase the hold capacity, and those carrying passengers in addition. Unlike the bulk freighter, with its almost universal triple-expansion engine, the quadruple finds most favour on this class of ship. The package freighters carry their own cargo-handling machinery, the cargo being worked generally through the side gangways, and entirely so in the case of the passenger steamer, where the accommodation does not allow of hatches through the spar deck. The apparatus is peculiar to this class of steamer, and consists of a line-shaft, running the entire length of the 'tween deck cargo space, driven at a constant speed by an independent engine, and carrying a number of compressed-paper pulleys. Abreast each hatch two hoisting drums are placed, one end of each being formed into a smooth cast-iron wheel corresponding in position to the friction-wheels on the line-shaft. The drum-shafts, carried in eccentric bearings, are so arranged that the operator can, by means of a lever, cause the drum-wheel to come in contact with the revolving paper friction, or by a reverse motion bring it into contact with a stationary brake-block. In practice this proves to be a fast, efficient, and silent method of handling mixed cargoes of this class.

Passenger Steamers.—The passenger steamers on the Great Lakes abound in such profusion and represent so many differing types that a very general description of a few of the most notable must suffice in this paper. As indicating the enormous volume of the passenger business, statistics show that 16,000,000 persons annually are carried. The passenger season proper lasts only from the early part of June until the middle of September, but during this time the steamers are crowded to their utmost capacity. The development of the passenger steamer has been more gradual than that of the other classes of steamers referred to, and the types do not represent any radical departure from usual and accepted American practice, the chief characteristics being regularity of service and excellence of the accommodation provided.

The only exclusively passenger steamers on the lakes are those of the Northern Steamship Company, and Fig. 8, Plate XII., represents the North West, one of their two "through" steamers between Buffalo and Duluth. These steamers are 386 ft. long, 44 ft. beam, and 25 ft. deep, of the twin-screw type, and are most luxurious in their appointments.

The steamers engaged on Lake Erie, in the night service between Cleveland and Detroit, illustrate the growth of the paddle-wheel type in the three steamers which have been successively engaged on this route, and have each borne the name City of Cleveland. The first of these, now known as the State of Ohio, is 225 ft. long; she was built in 1880, and fitted with fifty-six state-rooms. The City of St. Ignace, 272 ft. in length, was built in 1886, with the number of state-rooms increased to 185, while Fig. 9 illustrates the present City of Cleveland, which was built in 1908. She is 402 ft. long, 54 ft. beam of hull, 92 ft. beam over all, and has 342 state-rooms. Her engines are of the inclined three-cylinder compound type, of 7000 indicated horse-power. In addition to her large passenger capacity, she is arranged for 1000 tons of general merchandise, stowed on the forward main deck.

A steamer is now under construction for this service 472 ft. long, 50 ft. beam, 94 ft. wide over all, which will have 436 state-rooms, and 9000 indicated horse-power in her propelling machinery.

The City of Erie, one of the night steamers between Buffalo and Cleveland, represents the highest development on the lakes of the paddle-steamer with engines of the "beam" type, which, although for many years the favourite design for this class of steamer, has now given way entirely to the three-crank inclined type. She is 324 ft. long, and has a compound engine of 6000 indicated horse-power, the high-pressure cylinder being 52 in. in diameter by 95 in. stroke, and the low-pressure cylinder 80 in. in diameter and 144 in. stroke, both acting on a single beam.

Car-Ferries.—The car-ferries of the Great Lakes, all of which are owned and operated by the railway companies, are divided into two classes—those for river service, and those specially constructed for cross-lake traffic. The earliest ones are of the former type, introduced in the 'seventies to supersede the then existing slow and costly method of unloading merchandise from the train, ferrying across the rivers, and re-loading on the other side. This class of ferry is peculiar on the lakes to the rivers connecting Lake Huron and Lake Erie, where bridging has never been considered feasible, and tunnelling is only a matter of recent accomplishment, and for many years the entire railroad business across the Detroit River, between Detroit and Windsor, and that of the St. Clair River, between Port Huron and Sarnia, was carried by means of them, and it is estimated that in 1907 some 26,000,000 tons were transported across in this manner, as well as from 25 to 30 passenger trains per day.

Ten ferries were employed continuously, and, although, since the opening of the Michigan Central Railway tunnel under the Detroit River four of these have been withdrawn from the service, the remaining business is still very considerable. Operating always in still water, these river-car ferries are built with low freeboard and flat clear decks, the propelling machinery, in the case of the screw-boats, being entirely under the car-deck, and well out in the wings in the paddle type, in which there is no cross-shaft, the wheels being independent and driven by separate engines. All the river ferries are "double-enders," fitted with two to four tracks, and can accommodate from eighteen to twenty-four freight cars. These are loaded from connecting shore tracks, an "apron," or hinged section, of the dock being fitted at the end of the loading slip to provide for the fluctuation of the water-level. Regular service is maintained all the year round, the steamers being specially constructed for ice-crushing during the severe winter weather.

Fig. 10 shows one of the earlier type of river car-ferries, propelled by paddle-wheels, transporting a passenger train and breaking her way through the ice on the Detroit River. The later types of these vessels are fitted with two propellers at each end.

The principal routes of the lake car-ferries are across Lake Michigan, the Straits of Mackinac and Lake Erie. On the former about thirteen of these ferries are in operation, the Père Maquette Railway making connections between Ludington, Mich., and several ports on the Wisconsin side, while the Ann Arbor Railway operates a fleet from Frankfort, Mich., to cross-lake ports, the routes varying from 60 to 90 miles in length. These are powerful twin-screw steamers, averaging 350 ft. long, with capacity for thirty loaded freight-cars carried on tracks laid on the main deck. The sides are carried up some 18 ft. to a shelter-deck covering the entire ship, except a small portion aft where the stern is left open for the loading and unloading. Passenger cars are not carried on these ferries, accommodation for passengers being provided above the shelter deck.

Across the Straits of Mackinac two car-ferries have been operated since 1888, carrying both passenger and freight trains between Mackinaw City and St. Ignace, a distance of 7 miles. On account of the difficulty in keeping this service open during the winter months, owing to the "ice packs" which occur in the Straits, these steamers are fitted, in addition to the usual propeller aft, with one at the bow, driven by an independent engine, to assist in breaking out a channel. During the summer months the forward one is not operated, the engine being disconnected and the propeller allowed to revolve freely.

The Lake Erie car ferries are exclusively used in transporting Ohio and Pennsylvania coal to Canada, several routes being operated. The largest of these steamers have a capacity for thirty coal-cars of 50 tons capacity each.

TANK TESTS ON MODELS OF SUBMARINES.

By Mason S. Chace, Member

*Results of Experimental Tank Tests on Models of Submarines.**

The model tests, the results of which are here recorded form a part of a series of a number of models of submarines tested at the United States Experimental Model Basin, Navy Yard, Washington, D.C., for the author. This paper presents the results of tests of four models, all derived from the same parent form. These tests comprise speed and power tests of the four models; also an experimental determination of the stream-lines, or lines of flow, around one of the models.

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 5, 1911.

WASHINGTON D C NOV 1 1910

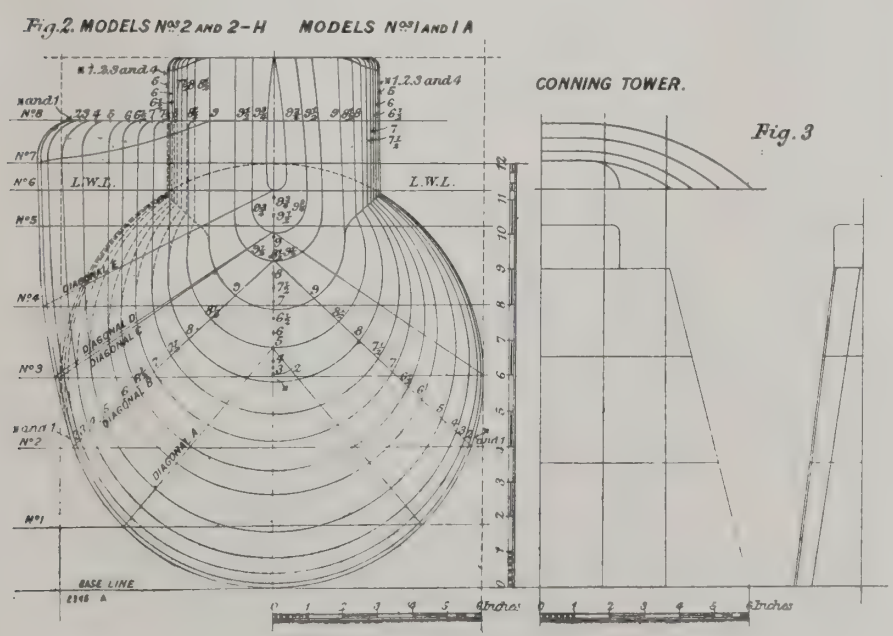

Fig. 2. MODELS Nos 2 AND 2-H MODELS Nos 1 AND 1 A

Fig. 3

Description of the Models.—These models are of a simple, elementary form, with the bow and stern exactly alike, and of canoe shape. All four models have a uniform spindle diameter of 12 in. Figs. 1 and 2 show the combined body-plan of all models, and the form of conning-tower used in the tests is given in Fig. 3. The sheer and half-breadth plans, also the diagonals and curves of sectional areas for models Nos. 2 and 2 H, are given in Fig. 1 and 2.

Model No. 1, the parent form, has circular cross-sections. All models, with the exception of model No. 1 A, have a length on the load water-line of 12 ft., and a parallel middle body 14.4 in. long.

Model No. 1 A was derived from Model No. 1 by the removal of this parallel middle body and a consequent reduction of the load water-line length to 129.6 in.

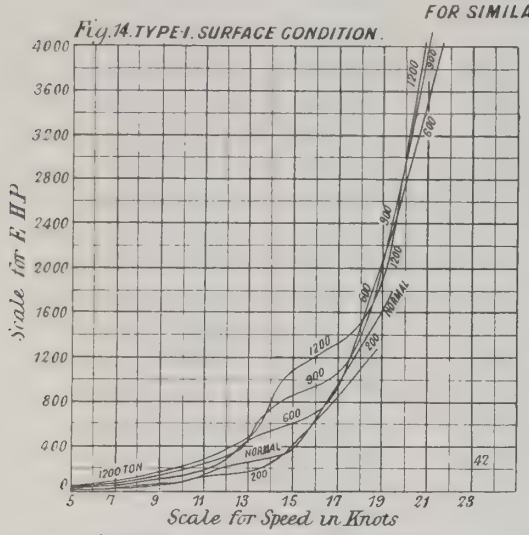
Model No. 2 was derived from model No. 1 by slightly fining the ends on about one quarter of the length from each end, and changing the shape of the end sections from circular to oval.

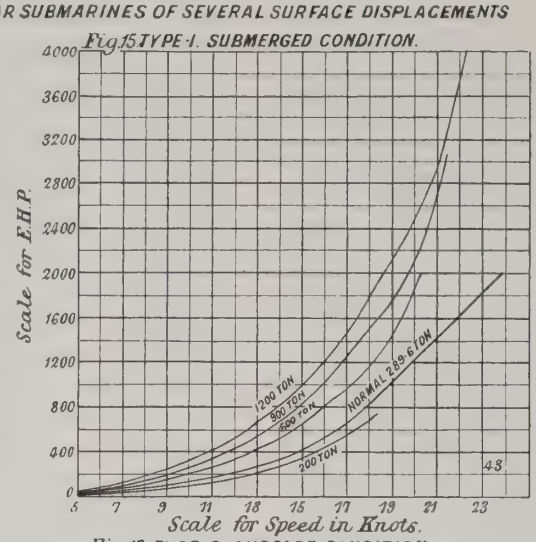
Model No. 2 H was derived from Model No. 2 by hipping out amidships, above the axis of the spindle, and fairing in with the original form.

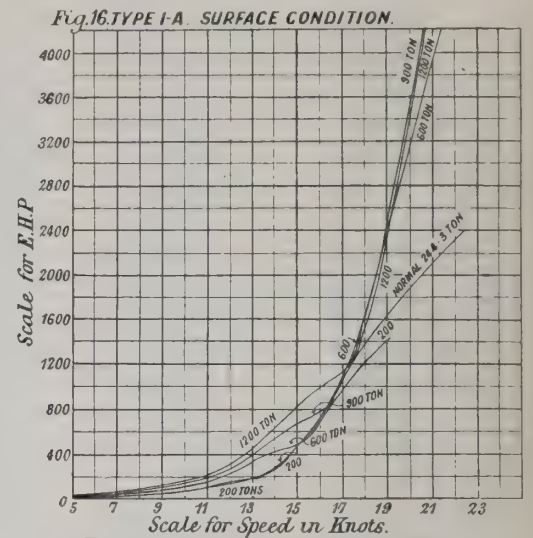
The principal dimensions and characteristics of these models are given in the table which follows (see page 69). This table is prepared on the assumption that the models represent full-sized vessels, on the scale of 1 in. equals a foot, and all figures in the table are for such full-sized vessels floating, or submerged, in sea-water. The displacement and wetted surface of the conning-tower appear at the bottom of the table. The figures pertaining to the conning-tower are not included in others given in the table.

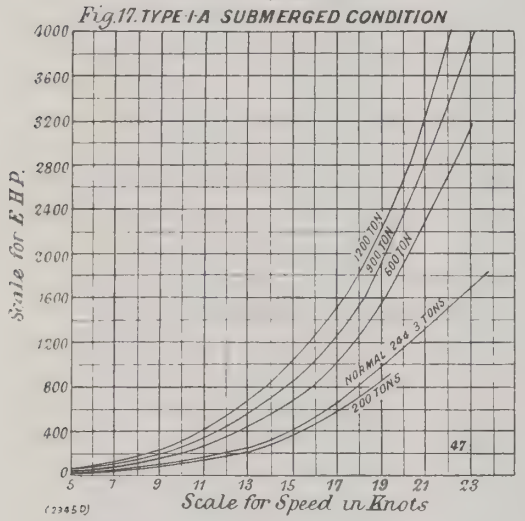
The principal dimensions and elements of the types which these models represent are shown on Fig. 4,

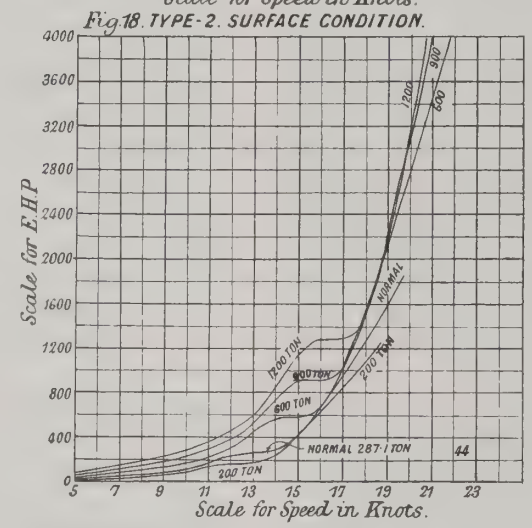
CURVES FOR EFFECTIVE HORSE-POWER
FOR SIMILAR SUBMARINES OF SEVERAL SURFACE DISPLACEMENTS

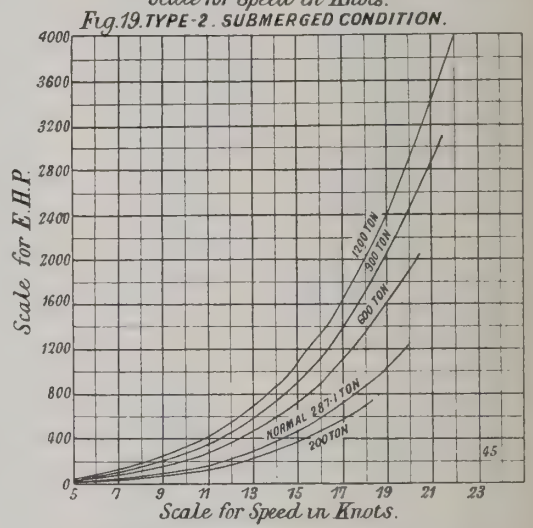












transmitted to the models by means of a vertical towing-bar, fitted with a roller, which bore on the forward vertical face of the towing-box in the model at a point slightly below the load water-line, when the models were at rest. The vertical distance separating the point of application of the pull of the carriage and the line of resistance of the models probably has more of an effect on the trim, at different speeds, in the case of models of submarines, with their comparatively small longitudinal stability, than it does in the case of models of ships of ordinary form.

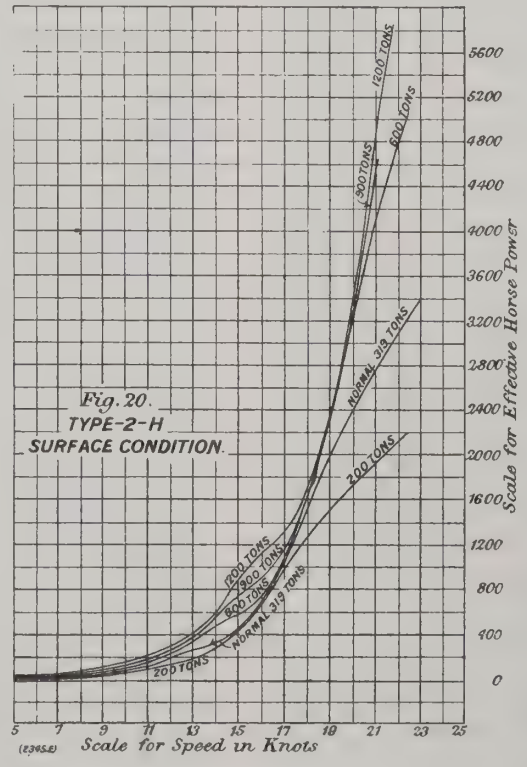
When towed awash, or submerged, the models were held rigidly in a horizontal position, at the required depth, by two vertical fins. After the completion of each series of submerged runs, the fins were run to determine the fin-resistance. The resistance of the model was obtained by deducting the fin-resistance from the total resistance of model and fins. The resistance of the fins, when run alone, and when run in conjunction with the model, is probably not the same; also the model resistance, submerged, when held horizontal may not correspond exactly with that of the full-size vessel, running submerged, at a corresponding speed, in its position of equilibrium. The curves of model resistance, submerged, show that within the limits of these experiments the submerged resistance diminishes with an increase of submergence. Even when the top of the spindle-hull is submerged to a depth of 2.4 diameters, all effects of surface disturbances are not eliminated.

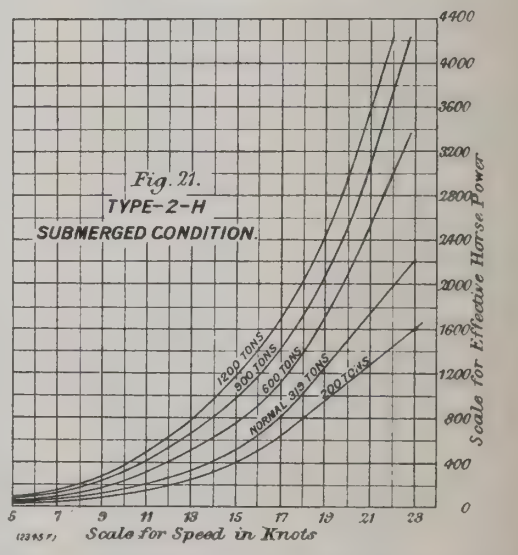
The resistance of the conning-tower, as obtained from model tank tests, is likely to be underestimated rather than given its true value, in per cent. of the total resistance, running submerged, owing to the presence of the fins in line with the conning-tower.

These models were tested without appendages, so in using curves of effective horse-power developed from the results of these tests to power full-sized vessels, with appendages, due allowance must be made for the added resistance of the appendages. The resistance due to appendages of submarines, such as keels, rudders, struts, shafting, torpedo-tube projections, &c., in excess of the bare hull resistance, can generally be closely estimated from the results of model tank tests, but it is sometimes found to be in excess of what the model tests indicate. This may be due to the presence of eddies, in the case of the full-size vessel, which do not exist for the model. It is often found difficult to obtain consistent results when it is attempted to separate the appendage resistance up into its component parts. The total resistance, due to all appendages, can generally be closely estimated in per cent. of the bare hull resistance, or allowed for in the choice of a propulsive coefficient, from known data regarding similar submarines.

The curves of model resistance, in Fig. 5, show a well-defined hump, for surface running, and also for running with the top of the superstructure awash, at a model speed of 3.5 knots, or a value of $\frac{V}{\sqrt{L}}$ equal to about 1. This hump is followed by a hollow, at a speed of 4 knots, beyond which the curve rises rapidly. The hollow in the curve of resistance occurs at a "critical" speed in so far as a change of trim is concerned. The curves of level, at the top of Fig. 5, show that beyond the speed of 4 knots the bow rises and the stern settles rapidly. Referring to the photographs, Figs. 6 to 13, Plate XIII., which show the wave profiles at various speeds, it may be noted that at the speed of 3.51 knots, corresponding to the hump, the hollow of the bow wave is forward of amidships, and that at the speed of 4 knots it is nearly amidships, with the second wave-crest at the stern. At the higher speeds this hollow moves aft, and the second crest passes astern.

All four models, even when driven at much higher





speeds, in proportion to the lengths, than could be attained by full-sized submarines, exhibited a marked tendency to trim by the stern, or "squat." This quality is desirable, in the case of submarines, for a tendency to "root" might become dangerous, owing to the comparatively small longitudinal stability, low freeboard, and small emerged displacement of such vessels.

Speed and Power-Curves for Full-Sized Vessels—Curves of effective horse-power for surface and submerged running, developed from the curves of model resistance, are shown in Figs. 14 to 21, inclusive. Each diagram gives curves of effective horse-power for similar full-sized vessels, of several surface displacements from 200 tons to 1200 tons. For convenience in making comparisons the results of the curves of effective horse-power are put in the form of contours of effective horse-power, plotted on speeds and displacements. shows the contours of effective horse-power for surface running, and Figs. 26 to 29, page 67, for submerged running.

Curves of residuary resistance in pounds per ton of displacement, plotted on values of $\frac{V}{\sqrt{L}}$ applicable to vessels of any size, are shown in Fig. 30 for the four types, under surface and submerged conditions.

The curves of effective horse-power all rise rapidly beyond a value of $\frac{V}{\sqrt{L}}$ equal to about 1.25, they also cross and re-cross at different speeds, showing that at these speeds vessels of different lengths and displacements take the same power to drive. At the high speeds the contours of effective horse-power, particularly for surface running, approach and become nearly vertical. While large submarines, suitable for high speeds, would probably not be designed by increasing all dimensions in the same proportion, these curves can be used in making different speeds, and made the humps and hollows of the curves of resistance come at lower speeds.

The removal of the parallel middle body from type No. 1 to produce type No. 1 A has effected a reduction in length of 14.4 ft., a reduction in the ratio of length to beam of from 12 to 10.8, and a reduction in the total displacement, submerged, of 54.5 tons, but a material increase in the displacement-length coefficients. These changes have resulted in a reduction of the longitudinal coefficient, surface condition, from 0.64 to 0.60.

A comparison of the curves of effective horse-power of the two types shows that a vessel of type No. 1 A requires materially less power to drive, surface running, than a vessel of the same displacement type No. 1, until speeds where $\frac{V}{\sqrt{L}} = 1.2$ are reached. For a speed such that $\frac{V}{\sqrt{L}} = 1$, surface running, the residuary resistance of type No. 1 A is only one-half of that of type No. 1. For $\frac{V}{\sqrt{L}} =$ even in so far as the use of model tests are concerned. The speed problem is a much more complicated one, in the case of submarines, than in that of any other type of ship, as submarines are designed for both surface and submerged running, and a choice of factors favourable in one condition may be extremely unfavourable in the other. While the percentage of the displacement which can be assigned to propulsion, in the case of submarines, is smaller than in that of surface torpedo-boats, the weight so assigned must be divided between two power systems, one for surface running and the other for running submerged. All systems at present in use for submerged propulsion are extremely inefficient.

To-day the question of how to best increase the speed of submarines is the most important one connected with their future development, particularly as a further menace to the battleship, whose operations are practically restricted to the high seas, owing largely to what the submarine can now do, and ignoring the great possibilities of the future use of aerial craft, especially in connection with coast defence.

Increased speed, particularly surface speed, combined with increased radius, is required of the sea-going submarine. This means increased dimensions, even if important improvements are made in the power systems to be

comparisons, and in a preliminary investigation of speed possibilities.

Comparisons and Observations.—In comparing the results of the tests, let us first consider the type represented by models No. 1 and No. 2. The variation made in model No. 1 to obtain model No. 2 was quite small, consisting only of a reduction in the total displacement, submerged, of 3.2 tons, or less than 1 per cent., which reduction was made by fining the ends. This fining process was apparently not beneficial from the point of view of resistance. Inspection of the curves of effective horse-power, Figs. 14, 15, 18, and 19, on page 66, shows that for both surface and submerged running, except in the "hollows" of the curves (surface condition) which cannot be utilised, and at very low speeds, the finer model No. 2 takes more power to drive than No. 1, until very high values of $\frac{V}{\sqrt{L}}$ are reached. The wetted surfaces for the two models are practically the same. The curves of residuary resistance, on Fig. 30, show the difference in the residuary resistance of No. 1 and No. 2, for different values of $\frac{V}{\sqrt{L}}$. A possible explanation of these results is that fining No. 1 to produce No. 2 has shortened the wave-making length of No. 2, and brought about the interference of the bow and stern wave systems at lower about 1.2 the residuary resistance curves coincide, and for a value of $\frac{V}{\sqrt{L}}$ greater than 1.3 the residuary resistance of type No. 1 is less than that of type No. 1 A. For submerged running the two types take practically the same power, and the curves of residuary resistance cross and re-cross.

While type No. 2 H was derived from type No. 2, by hipping out amidships, we will briefly compare the power necessary to drive vessels of the same surface displacements of type No. 1 A and type No. 2 H, as these types have the same ratio of length to beam, and the displacement length coefficients are about the same. The wetted surface per ton of displacement for type No. 2 H is less than for type No. 1 A.

For surface running, type No. 1 A generally takes slightly less power than type No. 2 H. The residuary resistance in pounds per ton of displacement is less for type No. 1 A, at all speeds, surface or submerged, than it is for type No. 2 H. The power required, when submerged, is greater for type No. 2 H than for type No. 1 A, owing to the increase in the submerged displacement for the same surface of displacement.

We would have to go beyond the limits of this paper to give due consideration to all of the various factors which enter into the speed problem in the design of submarines, adopted in the future. Sea-going submarines of a surface speed of 20 knots, combined with a submerged speed of 10 knots, have already been proposed as an immediate future development.

We may note, from an inspection of the curves of effective horse-power for type No. 2, Figs. 18 and 19, page 66, that a vessel of this type, bare hull, with a surface displacement of 1200 tons, a submerged displacement of 1536 tons, and a length load water-line of 232 ft., would require 330 E.H.-P., or, roughly, 660 indicated horse power, to attain a submerged speed of 10 knots, and 3140 E.H.-P., or, roughly, 6280 indicated horse-power, for a surface speed of 20 knots. A vessel of the same displacement designed for these particular speeds could be made more economical.

Experimental Determination of Stream-Lines for Surface and Submerged Running, Model No. 2.—The same method of investigation was followed as has been successfully used at the model basin* in the case of the models of ordinary types of ships, other than submarines.

The surface of the model is coated with a mixture of glue and sesqui-chloride of iron, which is allowed to dry

* See "An Experimental Investigation of Stream-Lines Around Ships' Models," by Naval Constructor D. W. Taylor, U.S.N., Transactions of the Society of Naval Architects and Marine Engineers, 1908

on for about twenty-four hours before the model is put into the water and towed. While the model is under way, a strong solution of pyrogallic acid is ejected from holes bored through the model from the opposite side. It mingles with the water, and flows aft as part of it. The acid which comes in contact with the coating of chloride of iron forms ink, and leaves a black streak on the model, which marks the line of flow past the hole. This streak widens, and becomes indistinct as it passes aft, but its centre can be accurately located for a distance of 2 ft. or 3 ft. abaft the hole. The model is taken out of the water after each run, and the centre of the streak traced as far as possible, and then a new hole is made from which to eject acid on the new run.

In some cases the first holes used were near the stern, so that the lines of flow at the stern could be sharply defined before the model coating in that vicinity became darkened. Some of the lines of flow were traced for only a part of the length of the model. It was necessary to re-coat the model several times during the course of the experiments, and although, during each run, two or three holes were used at a time for the ejection of acid, the process was a slow one.

In the determination of the stream-lines for surface running the model was towed at 4.33 knots, corresponding to a speed of 15 knots for the full-sized ship. The resulting stream-lines, also the wave profile, are shown by the full-lettered lines on Figs. 31 and 32, page 68. These stream-lines, for surface running, have the same general characteristics as might be expected from a study of the results of similar tests made with ships' models, already referred to.

The water from forward, starting from near the surface, flows downwards, and tends to pass, or actually passes, under the model amidships, and then flows up aft. The water which follows the line A first diverges from the centre-line, and then approaches it as it comes amidships. From amidships aft this water passes first outward and upward, and then again approaches the centre-line as it passes upward and aft. Changes in direction of the stream-lines and changes in the form of the wave profile correspond, and the direction of the stream-lines is apparently influenced to a considerable depth by the form of the waves.

In determining the stream-lines for submerged running the model was towed at 2.9 knots, corresponding to a speed of 10 knots for the full-sized ship. The top of the spindle hull was submerged to a depth of 2.4 diameters. The model was probably not deeply enough submerged to eliminate all possibility that the stream-lines would be affected by surface disturbances. The resulting stream-lines are shown by the dotted, numbered lines on Figs. 31 and 32. The marked difference between the general direction of the stream-lines in the surface and submerged conditions is notable.

In the submerged condition, water starting from forward near the top of the model takes first an upward course, and then a nearly horizontal one as it flows towards amidships. Forward water, further below the top of the model, starts to flow downward, and then changes its course to a horizontal one long before the middle of the model is reached. Well aft the nearly horizontal stream-lines turn sharply upward as they approach the centre line. While a knowledge of the direction of flow of the water in contact with the hull is useful in fixing on the location of various hull appendages, such as keels, struts, rudders, torpedo-tube projections, &c., it is evidently much more difficult to locate appendages in a way not to seriously interfere with the direction of this flow, in the case of submarines, where the stream-lines have a double direction of flow, than it is with ordinary ships. The possible effect of the direction of the stream-line flow, submerged, on the stability of motion, submerged, of submarines of various forms and dispositions of submerging rudders, and different appendages, brings up many interesting questions.

FIFTY YEARS' DEVELOPMENTS IN MERCANTILE SHIP CONSTRUCTION.*

By S. J. P. THEARLE, D.Sc., Chief Ship Surveyor to Lloyd's Register, Member of Council.

FIFTY years ago, when the Institution of Naval Architects came into existence, some of the ships of the mercantile marine were being built of iron and some of wood, while a smaller proportion of new vessels were of composite construction. Iron as a material for ships had distinctly established itself, and yet wood as a material had not wholly given place to it. There were still many builders, and indeed many owners, who maintained a preference for the older material, while the wishes of those who desired to combine the structural advantages arising from the use of iron with the freedom from fouling due to a copper-sheathed bottom when on a long voyage under sail, were satisfied by the composite system. The s.s. Himalaya, built at the Thames Iron Works in 1853, and acquired by the Admiralty for transport service during the Crimean War and for many years afterwards, is an instance of an excellent iron vessel built prior to the Institution's birth. An examination of this old vessel, still doing duty as a coal-hulk at Devonport, will show that even so far back as 58 years ago, our foremost iron shipbuilders could design and build a good ship, notwithstanding the limitations due to the comparatively primitive state of the rolled-iron industry of that date. The dimensions of the Himalaya were 340 ft. by 46 ft. by 21 ft. 4 in., which were those of a very large vessel at that time, her displacement being 4690 tons.

But, large as was the Himalaya compared with the average mercantile vessel of 1853 (for she was originally built for the P. and O. Company), she was dwarfed into comparative insignificance by the Great Eastern, built at Millwall by Mr. Scott Russell in 1857. As will be remembered, the dimensions of this vessel were as follow: — 679 ft. 6 in. by 82 ft. 8 in. by 31 ft. 6 in., and when they are compared with those of the largest mercantile steamers existing in 1893, viz., the s.s. Campania and Lucania, which were then built for the Cunard Company, it will be admitted that the Great Eastern of 18,915 tons register was as one born out of due time. Had there been no Great Eastern to take into previous account, a consideration of the progress of mercantile shipbuilding in the fifty years of the Institution's existence would have shown a gradual development throughout. But, with such a vessel already in existence, the earlier years would seem rather to have been a period of decadence, were it not for the fact that, great as was Scott Russell's vessel as a specimen of shipbuilding, she was not a success as a commercial venture, nor was she adapted to profit-making; which is, after all, the only safe criterion by which to judge the merits of a mercantile vessel. The Great Eastern showed possibilities in iron ship construction, having regard to the materials available at the time for the purpose, and she further showed what should be avoided. It is only fitting that an Institution which owes its existence largely to the energy, foresight, and scientific ardour of Scott Russell, should now, in the fifty-first year of its age, bear public testimony to the genius of that great man, and if we cannot set down the name of the Great Eastern in the list of commercially successful vessels, yet we are able to recognise in that noble specimen of naval architecture a piece of work which, having regard to the time and circumstances of its production, is still without rival.

In the year 1860 the mercantile marine of the United Kingdom consisted of 27,663 vessels, of 4,658,687 tons net register, of which by far the greater part was of wood. The exact separate tonnages of wood, iron, and composite vessels of that date are, however, not now available. Of the total tonnage in 1860, 25,663 vessels, of 4,204,360 tons net, were propelled by means of sails, and 2000 vessels, of 454,327 tons net, were steamers.

At the end of December, 1909, the merchant shipping of the United Kingdom consisted of 21,189 vessels, of 11,585,878 tons net, or 18,402,201 tons gross register. Of these, 11,797 vessels, measuring 10,284,818 tons net, or 16,994,732 tons gross, were steamers, and there were 9392 sailing vessels, of 1,301,060 tons net, or 1,407,469 tons gross register.

From these figures it will be seen that there were 6474 more vessels in our mercantile marine in 1860 than there were in 1909, but the net tonnage in the latter year was 11,585,878 as compared with 4,658,687 tons in the former year, showing an increase in the 49 years of 6,927,191 tons net register.

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 6, 1911.

But this does not adequately indicate the growth of the mercantile marine in that time. To realise better the expansion which had taken place, it should be noted that the growth in steamer tonnage was from 454,327 tons to 10,284,818 tons, while the reduction of sailing tonnage was from 4,204,360 tons to 1,391,060 tons.

It is usual to compute that a ton of steamer tonnage is at least equal to 3 tons of sailing tonnage as far as regards cargo-carrying capability in any stated time, say, for instance, one year; this is due to the greater speed with which the steamer performs her voyage, and the greater despatch she gets at her port of loading or discharge. In point of fact, the ratio is even greater than 3 to 1, and is a continually increasing one. But taking it at 3 to 1, it would appear that the ratio of cargo-carrying capability of the British mercantile marine in 1909, compared with that of 1860, is as 32,155,514 to 5,567,341, or nearly as 6 to 1. Considering that a ton of steamer capacity is so much more now than it was in 1860, the actual ratio is even still greater than this.

Not only has the total tonnage grown enormously in the fifty years, but the average size of ship has also grown at perhaps an even greater rate. The average tonnage of the sailing vessels of the Mercantile Marine of 1860 was 164 tons, and that of the steamers was 227 tons. A vessel of 1000 tons was then considered a large one, the Great Eastern notwithstanding.

As was stated in a paper contributed by the writer to this Institution in 1907, the average tonnages of the cargo steamers afloat in 1870, 1880, 1890, and 1900 were respectively about 870 tons, 1330 tons, 1500 tons, and 1900 tons. In the year 1911 the average tonnage is about 2,300 tons. In the same paper the average gross tonnages of the cargo steamers built in the years 1870, 1880, 1890, and 1900 were stated to be respectively 1050 tons, 1580 tons, 2150 tons, and 3000 tons. The average gross tonnage of the cargo steamers built in 1910 was rather more than 3000 tons.

In 1860 the length of an average cargo steamer, as then being built, was under 200 ft., but by 1911 it had reached to from 350 ft. to 400 ft.

The form of midship section which prevailed in 1860 is shown by Figs. 1, 2, and 3, page 70, which represent respectively iron and composite sailing vessels and a cargo steamer. Fig. 4 shows a steel passenger steamer of the year 1883, and by referring thereto it will be seen that, although the section was fuller than in 1860, it still had a fair rise of floor, and a well-rounded bilge. The midship sections shown by Figs. 5 and 6 indicate the extreme flatness of floor and the squareness at bilge which is now a common feature in ocean steamers.

Rules had been prepared and published by Lloyd's Register for the building and classification of iron ships about 1855, and as might have been expected, produced as they were at a time when wood construction largely predominated, the classification of iron vessels under these rules was expressed in terms of years. Indeed, it was not until 1863 that the term of years criterion of a vessel's insurable qualities was discontinued, and its place taken by the letter designations $\frac{A}{A}$ $\frac{A}{B}$ and $\frac{A}{C}$, which expressed in a comparative manner the relation borne to a ship of the first class. In the year 1867 this mode of designation and comparison was superseded by the numerical one 100 A, 95 A, 90 A, 85 A, and 80 A; and up to the present time 100 A represents the highest classification of an iron or a steel vessel in Lloyd's Register.

By the year 1860 iron mercantile ship construction had assumed a definite character, and as regards sailing ships and the great bulk of steamship tonnage, there was not much evolutionary change visible for nearly twenty years after, except as regards the question of size and the proportion borne by iron vessels to the total number built, which was all the time an increasing one.

The frame of an iron ship was still, as it had been from the first, formed of an angle iron and a reversed angle riveted back to back, from the upper turn of the bilge to the gunwale, and riveted respectively to the lower and upper edges of a floor-plate below the upper turn of bilge. Beams were formed at first of plates with double half-round irons on the lower edge and double angles on the upper edge, and this was the kind of beam fitted in the Himalaya. When progress in rolled iron manufacture had reached a more advanced stage, a bulb-plate took the place of the double bars of half-round section, and later on the Butterly Company produced a rolled section equivalent to the bulb-plate and the double angles. Keelsons were of many different forms, ranging from the "box" keelson, which was inaccessible, and consequently could not be kept painted and clean, to the ⊤ shaped keelson formed of a plate with double ⊥ angles on upper and lower edges which still survives in the exceptional cases where the vessel has not a cellular double bottom. There were from an early date continuous centre-line keelsons having floors united to them, and intercostal centre-line keelsons associated with continuous floors. There were centre-through-plate keelsons associated with bar keels and continuous vertical keelson-plates associated with flat-plate keels. Indeed, the possible varieties of centre keelson have not been much, if at all, amplified since the early sixties of last century, as illustrated in Lloyd's Rules of that period. Similarly as regards side keelsons, also bilge and side stringers, there was not much difference in practice for many years. The midship section shown by Fig. 1 is in most respects typical of the iron sailing vessel of 1860, but the ordinary keelson arrangement of that time is better shown by Fig. 2, which represents a composite sailing vessel of about the year 1867, while Fig. 3 is representative of the comparatively few mercantile steamers being built in the early sixties, and more

especially those intended for the coast trade between Newcastle and London.

It was at about that time that water-ballast tanks began to form a part of the bottom structure of steam colliers, and Fig. 3, page 70, shows a midship section of one of these vessels fitted with the McIntyre double bottom The story of the John Bowes, and the other early steam colliers, has often been told, and the McIntyre tank was long ago described in the Transactions of this Institution. This is not the occasion to repeat what has already been so well said on the subject, but it is necessary to at least make a passing allusion to it in such a paper as the present. Moreover, it should be recorded that, inasmuch as the cellular double bottom is to a large extent an evolutionary development of the McIntyre tank, so the early steam colliers were to that extent the progenitors of the typical mercantile steamer of to-day. It was not, however, until about the year 1880 that the cellular double bottom in anything like its present form appeared in

ships of the mercantile marine, although an arrangement somewhat like it had been adopted some years earlier in the armoured ships of the Royal Navy, but without the characteristic feature of the margin-plate at each bilge with its frame attachments, which then, and now (with but little modification), is peculiar to the mercantile steamer. Fig. 4, page 70, shows the midship section of a steel passenger steamer of 1883, and, as will be seen, it has a double bottom fitted with floors at alternate frames.

By the year 1887 cellular double bottoms were becoming very general in both cargo and passenger steamers, and yet as late as 1889 the two largest and fastest vessels in the Atlantic passenger trade were constructed without double bottoms and with ordinary floors and shaped keelsons standing upon them. A few years later, and only vessels built for carrying petroleum in bulk, and some of the smallest cargo steamers in the coasting trade, were being built in that way. Such is still the case to-day.

The modes of combining the materials in cellular double bottoms have, however, changed very much since the latter were first introduced into the mercantile marine. For some years it was sought to subordinate transverse to longitudinal strength in the bottom framing by making the side longitudinal girders continuous, and by fitting the floors intercostally between the girders. This was doubtless largely, if not wholly, due to the prevalence of a similar practice as regards the longitudinal frames of both the bottoms and sides of war vessels. Sometimes one longitudinal girder on each side was continuous and the others intercostal, thereby limiting the number of pieces composing a floor to two on each side of the middle line. In cases where the floors on each side were fitted in one piece they were spaced at alternate frames only, and these were associated with a greater number of longitudinal girders fitted intercostally in lengths of two frame spaces; brackets being associated with the intermediate frame and reverse angles. Such an arrangement is not unusual in vessels still being built, and it is shown by Fig. 4.

Gradually it began to be realised that with both outer and inner bottom plating, associated with a continuous centre girder, continuous margin-plates, and well-fitted intercostal side girders, there was ample longitudinal strength in the bottom. Moreover, the fact that continuous floors associated with intercostal side girders was found to be an arrangement admitting of more rapid and cheaper construction than any of the others, served at length to make it the most commonly adopted, and such is the case to-day. The midship section shown by Fig. 5 has a cellular double bottom framed in this way.

During the past year or two the question of double-bottom construction has received much attention from shipbuilders. It has been suggested that the strength of a cellular double bottom is in most cases in excess of the requirements arising from stresses at sea, and even from ordinary dry-docking. The necessity for carrying a certain quantity of water ballast has, it cannot be doubted, had more to do with fixing the depth of the floors and girders than strength requirements, and so it has happened that various arrangements have been devised for diminishing the weight of material in the double bottom without reducing its water-ballast capacity. Time will show whether any or all these arrangements will prove sufficient in the different circumstances which may arise, but it is believed that some of them, more especially that shown in Fig. 13, will be found to give satisfactory results. For the most part these designs consist in associating the ordinary floor arrangements spaced at two or three intervals apart, with intermediate combinations of strong bulb-angle frames and reversed frames having plate-brackets at their extremities. Longitudinal girders are fitted on each side of the middle line in number determined by the spacing of the floors and the breadth of the vessel.

Particular reference is made to this growth of double-bottom construction within the past fifty years, because the bottom has probably undergone at least as great a change as any other part of the vessel, and especially has this been the case during recent years

In recording recent developments in the structure of mercantile vessels, mention ought to be made of the rapidly-growing tendency during recent years to omit angle side-stringers in holds and to compensate for their omission by increasing the thickness of shell-plating. Not only does this detract in no degree from the strength of the structure, but it has the advantage of cheapening production and of affording greater facilities for cleaning the inside of the vessel after discharging a cargo. It should also be recorded that there is a growing disposition to increase the frame spacing of vessels under proper conditions of size of frames and thickness of shell-plating. The joggling of either plate-edges or frames in order to avoid fitting packing between the frames and shell-plating is now becoming a common practice at all our ports, and the same principle is applied also to steel decks and to inner bottom plating.

In considering the question of deck beams, one has at the same time to deal with that of pillaring, for the two are largely interdependent. In 1860 the pillaring of an iron ship followed the same principle as had up to then been the practice in vessels of wood. A pillar was placed under the middle of the length of every beam throughout the greater part of an iron vessel's length (see Figs. 1 and 2), and under alternate beams at the extremities of the vessel, where the beams were much shorter than at amidships. Pillars were also placed at the sides of hatchways in number proportionate to the length of the hatchway. Vessels were not so broad at that time as to require more than the middle line row to the beams clear of the hatchways. Subsequently, as vessels became broader, a row of quarter pillars was introduced on each side of the vessel, these being generally placed under alternate beams.

The time had not then arrived for shipowners to order ships to be designed without any hold obstructions such as pillars occasion.

The first step in a progressive direction was made when tubular pillars were introduced. These are, however, so expensive that even to-day the smaller sizes are but rarely used. Then came the "massed pillaring" arrangement, in which support to the deck is afforded by a few

very strong pillars placed under longitudinal girders which, in association with additionally strong hatch-end beams, distribute the localised support over the entire deck (see Fig. 5). This arrangement admits of many modifications and adaptations. The fewer the pillars the larger they must be, and the stronger must be the distributing girders; while the more numerous the pillars the smaller they may be, and strong girders are less necessary. The extreme case is that in which the only pillars are the bulkheads, and in which certain of the beams are made very strong, of arched form, and so associated with longitudinal girders and brackets at the bulkheads as to throw the entire weight of the deck on the bulkheads and the sides of the vessel. Great changes have been made during recent years in regard to this matter of beams and pillaring. Beams are now for the most part fitted at every frame. They are usually of bulb-angle or channel section when iron or steel decks are laid, and are connected to the sides of the vessel by bracket-knees. Beams of "Butterfly" section or built with bulb-plates and double-angle mountings, such as were formerly so common, are now not often used, and only when beams are fitted to alternate frames. Similarly "turned" and "slabbed" beam-knees are become practically things of the past. The contrast between the beam formed with a plate, double-angle mountings and double - cope - irons on the lower edge, as was fitted in the Hima- laya, and the rolled-beam sections as used to- day is very great, and so is that between the round-bar iron pillars and the built pillar, as shown in Figs. 1 and 5 respectively.

The stiffening of water-tight bulkheads has undergone many changes during these fifty years. In 1860 the only stiffening to water-tight bulkheads, other than that afforded by the several decks, consisted of angle-bars of reverse-frame size spaced about 30 in. apart. It must, of course, be borne in mind that there were usually more decks in a steamer of the small tonnages then being built than would be the case to-day. Nevertheless the bulk- head stiffening was usually very inadequate for resisting the pressure due to a hold being filled with water.

The influence of the Bulkhead Committee of 1891 is to be seen in the practice of to-day. But before the Bulk- head Committee sat, the Committee of Lloyd's Register had increased the stiffening requirements by making the vertical stiffeners of frame - angle size and by fitting horizontal stiffeners 4 ft. apart in addition. To this was subsequently added deep vertical webs at the middle line and on each side, in number determined by the breadth of the vessel, and this was supplemented by semi-box beam-stiffeners, where decks were not laid on the beams, and by fitting brackets to the heels of the vertical stiffeners and to the extremities of the horizontal stiffeners.

The general practice to-day is to use vertical stiffening only, and this is frequently formed by flanging the edges of the bulkhead plates, which for this purpose are arranged vertically. The stiffening of the bulkhead in the way of each 'tween deck and in the holds is governed by both the depth from the top of the bulkhead and by the height of the 'tween decks, or depth of hold, as the case may be. The stiffening of a transverse water-tight bulkhead, as now built in a mercantile steamer, is a reasonable one and in marked contrast with that of fifty years ago.

For some years after iron ships were first built they were fitted with wood decks, which covered only stringers and tie-plates—for iron decks were then unknown. With increase in size grew the necessity for providing strength in excess of that which was obtainable through stringers and tie-plates. At length iron decks were found to be a necessity, but, at first, they were covered with a wood deck flat. Ultimately the wood sheathing was discarded, except in passenger vessels and those intended for certain special trades; and to-day it is more usual to find un- sheathed steel decks than any other arrangement in cargo steamers. Of late years various preparations, of which the material known as "Lito silo" may be taken as a sample, have been extensively used to protect iron and steel decks from corrosion, and at the same time to afford the other advantages associated with a wood sheathing. Recent years have witnessed many impor- tant departures in steel ship construction. The first of these to claim attention is the turret steamer, shown in section by Fig. 6, page 70. These vessels were intro- duced by Messrs. Doxford and Co., of Sunderland, who have built a great many of them for many different owners, although of late the demand for them seems to have fallen off. Among the advantages of the turret system is that of a larger dead-weight carrying capacity than that of the normal type of steamer upon the same registered tonnage. It is also said of them that they are very sea- kindly in their behaviour. The "trunk" steamers shown by Fig. 7, page 70, were introduced by Messrs. Ropner, of Stockton-on-Tees, and are chiefly used for the convey- ance of ore, grain, and other bulk cargoes. Descriptions of vessels so distinct in character, and differing so much from the normal type, as are the "turret" and "trunk" steamers, would, it is thought, best proceed from those to whose design they are due, and it is much to be desired that Messrs. Doxford and Messrs. Ropner would favour this Institution in such a manner. The cantilever frame wing-tank steamer of Messrs. Sir Raylton Dixon and Co., shown in midship section by Fig. 8, has been described by Mr. Waynman Dixon before the Institution of Civil Engineers, but it is regretted that the Institu- tion of Naval Architects contains no record in its Trans- actions of a type of vessel which is not only structurally interesting, but which has the advantage of affording means for suitable immersion in a ballasted condition without an attendant excess of stability. The same may be said of McGlashan's side - tank steamer shown by Fig. 9, page 71.

Probably the most interesting of all the recent develop- ments in ship design is that of Mr. Isherwood, which is described in the Transactions of 1908,* and shown by Fig. 10. Upwards of ninety of these vessels, repre- senting about 356,000 tons gross, have been ordered by different companies, and forty of them have been built and are at sea. The experience so far obtained regarding their structural efficiency has been generally satisfactory. Such a distinct departure from previous shipbuilding practice must, of course, for some little time to come, partake of an experimental character, and one must be prepared to learn by "trial and error" regarding this as of all other modes of ship construction.

To do full justice to the subject of this paper, some further reference should be made to the composite system of construction, which between the years 1860 and 1870 seemed likely to wholly take the place of iron con- struction for sailing vessels. It was, indeed, favoured by some for steamships also. Fig. 2, page 70, shows the midship section of a composite sailing vessel, such as was being built in 1867. The system combined the strength of iron framework partially plated, with the advantages of a wooden skin to receive copper sheathing, and thereby avoid the fouling of bottom which was experienced in iron vessels. The sailing speed of iron vessels was con- siderably reduced, more especially on the homeward voyage, by reason of this tendency of an iron bottom to become rapidly foul in sea-water. The idea of a compo- site system of construction was probably due to the high freights obtained for prompt delivery of the early tea crop. The performances of the composite tea clippers will long be remembered, and even their names will not be forgotten. Very soon composite vessels were built for the Australian and East India trades also, and about the year 1867 there was a very considerable tonnage of composite sailing vessels being built in the United Kingdom in vessels of about 800 to 1,000 tons register. The system was, however, an expensive one to build, and it was soon found that the vessels were liable to special forms of deterioration, chiefly associated with galvanic action, which made their maintenance costly. The open- ing of the Suez Canal gave a new impetus to steam navigation, and within a few years afterwards composite vessels almost wholly ceased to be built for the mercantile marine.

The proportion of the sailing carrying trade performed by wooden vessels continued to be considerable for nearly twenty years after this Institution came into being. The writer of this paper found abundant occupation in the survey of wooden mercantile vessels, even up to 1200 tons register, between the years 1876 and 1880, and it may be said with perfect truth that never were wood vessels built so strongly nor so durably as when the time came for the building of them to practically cease altogether.

So far as we have gone, attention has been given only to the changes which have occurred in the material and the details of the construction of mercantile vessels in the course of fifty years. This does not by any means cover all the ground. On the contrary, it is doubtful whether the changes which have occurred in the outline design of steamers have not been at least as considerable as those relating to the details of construction.

In a former paper, already alluded to, the evolution of the cargo steamer was considered, and consequently it does not appear to be desirable to again go over the ground then traversed. Reference is invited to the paper referred to so far as regards the progress made in the design of tramp steamers in the course of fifty years and of the various stages through which those changes occurred. It is, however, necessary to give some atten- tion to the enormous strides made in the design and con- struction of passenger steamers, and more especially those engaged in the North Atlantic trade.

Neglecting the case of the Great Eastern as of one born out of due time, we see a growth of from 340 ft. to 850 ft. in length during that time, and in tonnage from 2960 tons to about 32,000 tons. In 1860 the fastest steamers in the passenger trade had no greater speed than 12½ knots; whereas to-day there are two vessels which are capable of averaging nearly 26 knots on a voyage from New York to Queenstown. (Fig. 11, page 71). The number of passengers carried in one of our largest steamers in 1860 did not exceed about 250, whereas to-day no less a number than 2600 can be con- veyed in one vessel between Liverpool and New York. To show the advances made in only fourteen years —viz., from 1893 to 1907—Figs. 11 and 12 may be advantageously compared. Fifty years ago passengers were for the most part berthed on one or more decks below an upper deck, whereas to-day a large part of the passenger accommodation is provided in roomy, well- lighted, and airy cabins situated above the upper deck. A comparison of the luxury attending steamer travel to-day with the conditions which prevailed in 1860 would demonstrate more clearly than in any other way to the "man in the steeet" the enormous strides in passenger steamship design which have been made in the interval. And to it all there have been added greater strength of structure, greater security against the ordinary perils of the seas, and greater regularity of performance.

Much of this development has been due to the substitu- tion of mild steel for iron, and even to the use of high tenacity steel for those parts of the structure subjected to the principal tensile stresses. How much of it is due to the improvements made in the marine steam-engine, and more particularly to the application of the steam- turbine to marine propulsion, I leave my engineering friends to say. Every advance in steel manufacture and in the rolling of plates and sectional material has been conducive to more efficient structural combination, and therefrom to stronger and better ships. The naval architect has received help from many sources, to all of which he bows in grateful recognition. The ocean pas- senger finds himself conveyed in faster and safer vessels than were conceivable when this Institution came into existence, and under conditions of comfort, and even luxury, which are unsurpassed in the best hotels. Such are some of the principal features which serve to indicate the progress of the past fifty years in mercantile ship construction. But finality has not yet been reached, nor is it likely to be in the near future, even if at any time. While these remarks are being put upon paper, the writer is daily, in the course of his official duties, being confronted with something new, which, if not always worthy of being described as progressive, is yet indicative of the restlessness of the age, and of the continual search which is being made for that which shall render existing tonnage obsolete. It is only in that way that progress is made, and while it undoubtedly happens that every step made is not a step forward, yet it must be remembered that without movement progress is impossible, and that he who never makes mistakes possibly never makes anything.

THE COPPER MARKET.—In their report, dated July 3, Messrs. James Lewis and Son state that there has been a good demand for copper during the past month, both American and European consumers buying freely, in- fluenced by the improvement in the statistical position, increasing consumption in the United States, and the greatly increased consumption of and export from Europe. Standard copper advanced from 55*l.* 2s. 6d. for cash, on the 1st ult., to 57*l.* 10s. on the 26th, when 58*l.* 2s. 6d. was paid for three months prompt, and the price subsequently receded to 56*l.* 12s. 6d. on the 29th, but recovered next day to 57*l.* On the 3rd inst. the closing values were 56*l.* 12s. 6d. cash, and 57*l.* 3s. 9d. three months, on disturbing political news. The month's sales amounted to 24,000 tons. American electrolytic sells at 12⅜ cents per lb., large quantities having been sold for export to Europe. Shipments from the United States during the past month amounted to 30,074 tons. The imports were 11,234 tons, and deliveries 15,319 tons greater than during the same period of last year.

COMPETITIVE DESIGNS FOR PLAN OF NEW CAPITAL CITY OF AUSTRALIA.—We have been privileged to see the maps, plans, conditions, and other information on this subject, which have just been received from Mel- bourne. The competition is, we believe, the most impor- tant one of the kind hitherto presented to architects, engineers, and town-planners, intensified as it is by the fact that it is for the only capital city, with the excep- tion of Washington, planned from the outset on virgin ground. The maps include particulars resulting from a close survey of the site, and are on a scale of 400 ft. to 1 in., with contour levels 5 ft. apart vertically. These contour lines, of course, stand first in importance, and form the chief guide to the design. Besides this there are geological maps and a report, meterological and other information, as well as two landscape drawings printed in colour. We understand that the Commonwealth Government look forward to getting the best possible design from among those architects, &c., who propose to compete, especially as town-planning has recently been a very live subject, more particularly in this country.

SIR ROBERT HADFIELD AT SHEFFIELD.—Sheffield, both from a practical and an academic standpoint, owes much to Sir Robert Hadfield, F.R.S., who has recently returned to this country after an absence necessitated by too com- plete a devotion to the gospel of the strenuous life. His enforced divorce from business has been utilised by him in making a journey round the world, and the observa- tions made on this have served as the text of two speeches recently delivered by him at public gatherings in Sheffield. At the first of these, held at the university, he expressed his acknowledgments for the honorary degree of Doctor of Metallurgy conferred on him by that corporation, an honour which he must appreciate the more in view of the great importance of the Sheffield Metallurgical School. From his speech Sir Robert had evidently returned more and more convinced of the prime importance of quality in manufactured goods, and this, we believe, is particu- larly true in the case of the export trade to new countries. An interesting point raised by Sir Robert was that he thought he had found evidence in the course of his travels that the production of steel by the fusion process was practised in the East 2000 years ago, and he is now having analysed and examined some tools from Ceylon dating back 1500 to 2000 years. He further noted that, on crossing the Pacific to the United States, his steamer took with it the first load of Chinese pig iron to be ex- ported. China, he stated, had the largest iron ore resources yet discovered, so that this initial shipment may mark the inauguration of a new era. The second speech to which we have referred was delivered to a party gathering, and this dealt, to some extent, with matters as to which opinions will always differ, since, in politics, the data from which conclusions are drawn are necessarily incomplete, and every man, in drawing his deductions, unconsciously includes what, to use a mathematical ex- pression, may be called certain "concealed co-ordinates," and, further, the average politician, unlike the scientist, is much more concerned in what may be said than in what should be said. One interesting statement in this speech was that the natural productions of America have now an annual value of 2000 millions sterling, a circum- stance which, as Sir Robert pointed out, greatly reduces the danger of experiments affecting the body politic, since the results of even a disastrous failure would be cancelled by the harvesting of a single good crop.

AGENTS FOR "ENGINEERING."

AUSTRALIA: Gordon and Gotch, Melbourne; Sydney; Brisbane; Perth.
Turner and Henderson, Sydney, N.S.W.
T. Willmett and Co., Townsville, North Queensland.
W. C. Rigby, Adelaide, South Australia.

LIVERPOOL: Mrs. Taylor, Landing Stages.
MANCHESTER: John Heywood, 143, Deansgate.
NEW ZEALAND: Gordon and Gotch Proprietary, Limited, Wellington, Auckland, and Christchurch.
NORWAY, Christiana: Cammermeyer's Boghandel, Carl Johans Gade, 41 and 43.
ROTTERDAM: H. A. Kramer and Son.
SOUTH AFRICA: Central News Agency, Limited, Head Office—Johannesburg; and Pretoria, Cape Town, Port Elizabeth, Bloemfontain, Durban, and their various branches and bookstalls throughout South Africa. Also Cape Town: Wm. Dawson and Sons, 31, Long-street.
SWITZERLAND: **Sole Agents for Advertisements:** The Dean-Mayer Company, Linkstrasse 39, Berlin, W. 9, Germany.
TASMANIA: Gordon and Gotch Proprietary, Limited, Launceston; Hobart.
UNITED STATES, New York: W. H. Wiley, 43, East 19th-street.
Chicago: H. V. Holmes, 957-958, Monadnock Block.
Sole Agents for Advertisements:—The Wm. S. Parry Co., 315, Dearborn-street, Chicago, and 366, Fifth-avenue, New York, U.S.A.

ADVERTISEMENT RATES.

The charge for advertisements is three shillings for the first four lines or under, and eightpence for each additional line. The line averages seven words. Payment must accompany all orders for single advertisements, otherwise their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper and on the inside pages may be obtained on application. The pages are 12 in. deep and 9 in. wide, divisible into four columns of 2¼ in. in width. Serial advertisements will be inserted with all practicable regularity, but absolute regularity cannot be guaranteed.

Advertisements intended for insertion in the current week's issue must be delivered not later than 5 p.m. on Thursday. In consequence of the necessity for going to press early with a portion of the edition, alterations for standing advertisements should be received not later than 1 p.m. on Tuesday in each week.

SUBSCRIPTIONS, HOME AND FOREIGN.

"ENGINEERING" can be supplied direct from the Publisher post free, for twelve months, at the following rates, payable in advance:—

For the United Kingdom	£1	9	2
For Canada—

NOTICE OF MEETING.

THE INSTITUTION OF MECHANICAL ENGINEERS.—On Monday, July 24, the Summer Meeting will commence with alternative excursions from Basel to Zurich, visiting on the way (*a*) Rheinfelden and Laufenburg, (*b*) Baden, including the works of Messrs. Brown, Boveri, and Co., (*c*) Rheinfelden, or (*d*) Wangen-on-the-Aare and Baden, including the works of Messrs. Brown, Boveri, and Co. On Tuesday, July 25, at 10 a.m., the President, Colonel P. E. Huber, or the Vice-President, Mr. E. Sulzer-Ziegler, of the Verein Schweizerischer Maschinen Industrieller, will welcome the President, Council, and Members of the Institution in the Aula of the Swiss Polytechnikum, after which papers will be read and discussed. The following papers have been offered for reading and discussion:—"Electric Traction in Switzerland," by Mr. E. Huber-Stockar; "Results of Experiments with Francis Turbines and Tangential (Pelton) Turbines," by Professor Dr. Franz Prásil; "Some New Types of Dynamometers," by Dr. A. Amsler; "Rack-Railway Locomotives of Switzerland," by Mr. T. Weber and Mr. S. Abt. "High-Pressure Water-Power Works," by Mr. L. Zodel; "Steam-Turbines," by Mr. H. Zoelly; "Modern Diesel Oil-Engines," by Mr. F. Schubeler. On Tuesday afternoon alternative visits have been arranged to the works of Messrs. Escher Wyss and Co., or the Oerlikon Machine Works, while an excursion on Lake Zurich has also been arranged at the invitation of the Verein Schweizerische Machinen Industrieller. In the evening, the Institution dinner will be held in the Tonhalle. On Wednesday, July 26, at 9 30 a.m., the meeting will be continued in the Aula, and papers will be read and discussed. In the afternoon there will be alternative excursions (*a*) to Winterthur, to the works of Messrs. Sulzer Brothers, and the Swiss Locomotive and Machine Company; (*b*) to Schaffhausen, (*c*) to Beznau. On Thursday, July 27, alternative whole-day excursions have been arranged to Glarus or Braunwald. On Saturday, July 29, Members will travel to Lucerne, *viâ* the Rigi-Kulm, this concluding the official arrangements.

ENGINEERING.

FRIDAY, JULY 14, 1911.

THE DIRECTOR OF NAVAL CONSTRUCTION.

THE announcement by the First Lord of the Admiralty of the impending retirement of Sir Philip Watts, K.C.B., from the post of Director of Naval Construction at the Admiralty is one of first importance in view of the great responsibilities attaching to the office and of the consequent necessity of securing a successor possessing the highest qualities to carry out the various and exacting duties. Sir Philip's demission of the position has not come as a surprise. It was known to many that for some time he has been contemplating the prospect of relief from the heavy task continuously imposed upon the Chief of the Constructive Department of the Navy, and the utilisation of his ability and experience in less onerous work. It is true that he has not held the office for as many years as some of his predecessors. The late Sir Edward Reed, K.C.B., was Chief Constructor of the Navy for only about seven years, but Sir Nathaniel Barnaby held that position, and the same post under the new designation of Director of Naval Construction, for about fifteen years; Sir William White, K.C.B., was in office for over sixteen years; and now Sir Philip Watts is retiring before the completion of his tenth year; but he has continued in harness until a later age, and it may also be said that he has made vaster changes and incurred greater responsibilities than those incurred within the same number of years in any period in the history of the Navy.

We have no intention of reviewing Sir Philip's work and its influence on naval architecture generally. That would be premature, for it is not yet completed. It is worth recalling, however, that, according to the Navy Estimates, Parliament has voted for shipbuilding, repairs, and maintenance of hull and machinery of ships of the Navy since he took office in February, 1903, a total of 168,700,000*l.*, excluding the cost of ordnance. That is a fair measure of the financial responsibility of the department. It would be easy to prove that efficiency in the fullest sense of that word has been achieved in the expenditure of this money so far as it depended on the department over which Sir Philip has presided. Warship design, it has often been said, is a combination of conflicting considerations. The strategist and the tactician lay down these considerations, so far as they affect offence and defence, which include speed as a matter of course, and it then becomes the duty of the naval constructor and the engineer to embody these so far as is possible within limits of dimensions and cost, which may or may not be reasonable. The advances made in any period of naval development cannot therefore be attributed to any one official at the Admiralty, but it cannot be forgotten that the ships designed for foreign Powers by Sir Philip, when at Elswick, were remarkable for those qualities of gun-power and speed which have been outstanding features of the recent additions to the British fighting fleet. The unification of calibre in guns was dictated by considerations of gun-control in battle practice; but the application of the principle devolved upon Sir Philip's department, with the difficulty of finding accommodation for magazines in positions dictated by the need for all-round fire, and of ensuring structural strength to withstand the stress consequent upon the greater muzzle energy of volley firing. It was quite consistent with fact, therefore, when the First Lord said, in announcing the impending retirement of the Director of Naval Construction, that Sir Philip "must bear upon his broad shoulders all the praise or all the blame which is to be associated with the name 'Dreadnought,'" but that he "would be comforted by the fact that, whatever else might be said of that type of ship, it is a type which has been much copied." A higher compliment can scarcely be paid, and with this remark we leave for the present Sir Philip's great services to the Navy and to the nation.

It is pertinent, however, to direct attention to the future, and to the qualifications which the Admiralty must seek for in the new Director of Naval Construction. Of the idea, once entertained, of deputing the duties and responsibilities to a Directorate composed of representatives of various departments at Whitehall, little has been heard lately. The idea cannot be commended, since devolution of responsibility is dangerous. A capable masterful mind is far more efficient from the creative standpoint when acting with undivided power and responsibility than when trammelled by colleagues equal in all things except ability, and therefore either acquiescent without attempting criticism, or critical without attempting original constructive design. At present the Board lays down the qualities of ships dictated by strategical and tactical considerations; the work of embodying these in ship design falls upon departments over which preside, and for which responsibility is accepted by, the Director of Naval Construction, the Engineer-in-Chief of the Fleet, the Director of Naval Ordnance, &c. This delimitation of work has continued since 1875 with unalloyed success, from the points of view of hull, engine, gunnery design, economy in cost, and efficiency in service. These have been years of great advance, alike in the qualities of individual ships, in the fighting efficiency and preparedness for war of vast fleets, and in the rapidity with which each step of possible opponents has been checkmated by the new ships. These are the true standards of test of the organisation at the Admiralty, and there is no evidence available to prove the need for any change.

The public and the profession are therefore very properly considering the qualifications for this important post, and the men available and capable of filling it. There may be gain in discussing the former subject; but we refrain from reflecting upon the latter, since the *rôle* of prophet is ever unprofitable. So far the struggle between nations has been confined to the peaceful victories in ship design, and, so far as finances allowed, to predominance in number. For years, too, we have enjoyed the flattery which comes from imitation; but it cannot be disparaging to the ability of the present or future officers of the Navy or Admiralty to say that the fact that we lead in construction and others follow may not always ensure victory in warfare, whether it come soon or is long deferred, especially as the advance of scientific education, begetting originality in conception, combined with increasing experience, encourages our friends in other countries to proceed on new lines, divergent in significant respects from those pursued by the British Navy. Of this fact there were ominous indications in the proceedings at the International Congress in London last week, the report of which is concluded in this issue. British methods are copied not merely as "fashions," but in large measure because of confidence in our prescience, resource, and experience. Such copying is not only complimentary, but satisfactory, since we lead, so long as it continues. With advancing education and increasing experience in the case of all foreign navies must come confidence and the determination no longer to follow. There is thus greater need in the future than in the past that the Director of Naval Construction should, above all else, be a man capable of original work, and of courage to evolve, and to enforce the acceptance of, new departures which are justified by their efficiency. In other words, our rate of acceleration in improvement must be increased, however difficult it may be in

view of the great achievements of the past, if we are to continue to maintain our supremacy so far as *matériel* is concerned.

It follows that work in a groove must be avoided, but it is certainly not a corollary that any one who has assisted Sir Philip in the past would, if elected as his successor, fail to show the originality and courage desiderated. It would be universally accepted as fair that the claims for promotion of existing members of the Royal Corps of Naval Constructors should first be considered, not alone because of their co-operation with the present and past holders of the office and of their right to reward for past services, but also because they have experience of the work and of the administration. Discrimination by the authorities responsible for the appointment must, however, necessarily begin with the generally accepted fact that experience of, and full acquaintance and long contact with, existing conditions tend to narrow the mental perception of blemishes and of the need of change. Another point upon which the public will have more cause to insist than those in authority is that there should be the highest independence of character. The post of Director of Naval Construction is one calling not only for high ability, but for courage and forcefulness in all technical matters. We have been fortunate in the past, but there have been occasions which have shown that this quality is requisite. British ships, in comparison with some ships designed and built by British firms for foreign navies, have often had their fighting efficiency depreciated by the fittings insisted upon by executive officers against the better judgment of designers ; and not infrequently, too, these have been needlessly multiplied in exposed positions, with the risk of disseminating destruction as a consequence of the action of explosive shells.

There are one or two distinguished naval architects not in the Admiralty service whose claims must be considered. It is essential that in such a case there should have been intimate practical contact with recent warship work, not only in the building of ships for the British Navy from the designs of Sir Philip Watts, but in the designing and construction of ships for foreign navies. Initiative, resource, and courage in the enforcing of new ideas can only be cultivated by practice. It is true that formerly nearly all our foreign clients for warships were disinclined to accept any departure from British Admiralty practice, and that the scope for originality was thus limited. One or two Powers still adopt the same attitude ; but most of them seek now the best that can be guaranteed by responsible firms, so that men possessing the qualities desiderated are obtainable from without the Admiralty. It is significant that Sir William White and Sir Philip Watts "stepped up higher" from one of our prominent naval construction firms, and the eyes of the public are naturally directed towards the men who are at the head of the designing and constructional staffs of such firms. There can be no question of the excellent and original work done with remarkable efficiency by Mr. J. R. Perrett, of Sir W. G. Armstrong, Whitworth, and Co., Limited, and Mr. T. G. Owens, of Messrs. Vickers, Limited, both of whom have been responsible in all respects for the design of the foreign ships built by the respective firms, and for the realisation of the results in those ships. These are the firms who have done more naval work for foreign navies than any other concerns in the world, and it is natural that the names of the officials solely responsible for their results should take precedence in the mind of the public as well as of the Board of Admiralty. The Admiralty must weigh well all the qualities of every available warship designer —experience, originative faculty, force of character, and administrative ability—and secure his services, irrespective of cost and of influence opposed to him, for the claims of naval efficiency should be held superior to all other considerations.

INTERNAL-COMBUSTION ENGINES FOR ELECTRIC POWER-STATIONS.

THE history of the development of electric generating stations in this country could almost be divided into a series of definite phases, or ages, each characterised by a different form of prime mover. Indeed, the history of electric generators could almost be similarly divided, since up to the latest developments of the steam-turbine, the electrical end of a generating set represented a form which had come into existence merely owing to the demand created by the development of its engine end. The phases into which electric generating stations could be divided might be known as the belt or rope-driven age, the direct-coupled high-speed-engine age, and the steam-turbine age. This classification is, of course, an approximate one only, and intermediate stages and individual cases have at all times cropped up which have interfered with its simplicity. None the less, this division into ages is a fair representation of facts, especially in this country, where, owing to so large a proportion of the electrical stations being under municipal control, there has been a great tendency towards definite lines of practice at particular times—a tendency towards what can best be described as the fashion of the moment. This tendency is natural enough, and is, indeed, inevitable, since it is no part of the business of a municipality to indulge in engineering experiments, but it is more than doubtful if it is in the best interests of engineering progress.

A tendency at any particular time towards uniformity of practice in generating-station design carries with it at least two evils. The first of these is illustrated frequently enough in the present steam-turbine age. If the type of prime mover to be adopted in any particular case is to be determined merely in terms of conformity with ruling practice, many examples will be found in which such conformity has resulted in the installation of unsuitable plant, or, at any rate, plant which was not the most suitable. Such examples are found at the present time in the form of steam-turbines of small capacity, having no advantages over reciprocating engines, and some disadvantage as compared with them, installed in some cases on quite a small scale in reciprocating stations, and having no justification beyond the fact that at the moment it is the fashion to instal turbines. The second evil is that a fashion in terms of any particular type of prime mover is likely to render the introduction of any new or improved form a matter of greater difficulty than need be. It may appear that the fact of the rapid advance of steam-turbines, and the supersession of direct-coupled high-speed engines by them, goes to show that this evil is small or non-existent ; but we think that an examination of the facts of the case will show this deduction to be unsound. Although in a way steam-turbines have superseded high-speed engines as the fashionable prime mover, they have not superseded them in the way that metallic filament incandescent lamps have superseded carbon filament lamps. The coming of the steam-turbine in generating-station practice was not properly an example of a new form taking the place of an older, since the extent of the work to be done increased so greatly at about the time of the introduction of the turbine. The general adoption of turbines was undoubtedly greatly assisted by the fact that they displayed such aptitude for driving the large electrical units which the rapid extension of the field and scale of supply rendered necessary. If the mission of turbines had merely been the taking over of work on the same scale as it was being carried out by reciprocating engines, it is doubtful if they would have made the rapid advance which has been seen.

During the last few years a new type of prime mover for generating-station use has come into the field in the form of the internal-combustion engine. A considerable number of installations of this class have already been put down and have proved successful. These have taken the form both of gas-engines and Diesel engines, and although the whole subject is still one around which a large amount of discussion revolves, it is by this time quite certain that either of these types is capable of forming the basis of successful plants. None the less the extent to which internal-combustion engines are used in generating stations is still very small as compared with steam plants. This is particularly the case as regards municipal stations, which, as we said, tend to illustrate, more than others, the fashionable practice of the moment. There are, however, several municipal stations both of the gas-engine and the Diesel-engine types, and the fact that the Incorporated Municipal Electrical Association devoted two papers to the question of internal-combustion-engine stations at their Sixteenth Annual Convention, which was held at Brighton the week before last, shows that municipal engineers in general are realising the importance of the matter.

It is an interesting speculation as to whether the next decade will see the beginning of an internal-combustion-engine age in generating-station design, in the sense that the present is the turbine age. Many gas-engine and Diesel-engine enthusiasts would undoubtedly say that it will, but, personally, we certainly have no intention of committing ourselves to any such prophecy. It will be remembered that Mr. Ferranti, whose prescience in some matters has been remarkable, decided against gas-engines in the large central generating-station scheme which he sketched in his presidential address to the Institute of Electrical Engineers. None the less, it must be remembered that this scheme was but a sketch intended rather to illustrate an idea than to stand for detailed practice. It is, of course, impossible for anyone to lay down the law as to the future line of development of any branch of engineering, and although non-believers in the internal-combustion engine may point out that the gas-engine is of much older standing than the steam-turbine, in the modern sense, and that the latter's relatively greater progress is proof of its superiority for generating-station use, they do not really make any case against the former. Their argument is a parallel one to that which might have been advanced to Sir Charles Parsons twenty-seven years ago, when it might have been pointed out to him that the inferiority of the turbine to the reciprocating engine was definitely established by the fact that it had been in existence since the days of Hero, and had been surpassed in every way by the reciprocating engine.

Although quite a good deal has by now been done in this country with gas-driven generating-stations, none the less the number of such stations is as yet insufficient for there to be any great amount of data available to enable them to be compared with steam stations. The local conditions and management of different stations varies so much that a large number of examples are necessary before it is possible to draw any general conclusion which may be considered fairly applicable to a particular type of plant. This fact, of course, militates against the rapid spread of new methods unless they show such remarkable advantages in the examples existing that it is impossible to ignore them. There are several large gas-driven stations now at work in this country, but they are mostly situated at private works or collieries, and in many cases the local conditions are specially favourable, so that the average municipal engineer probably feels that both the extent and conditions of the present practice are not such as to justify him in adopting a similar type of plant for his own use. An additional hindrance to the spread of the gas-engine for generating-station work lies in the obvious fact that it cannot be adapted to an existing steam station in the simple way that a turbine can be put down in a reciprocating-engine station. It involves a radical change of method.

If internal-combustion engines have an inherent and absolute superiority over steam-engines, they will ultimately come into extensive use and will take their proper place even in municipal stations ; but the process of change, especially at the present stage, must be a slow one. The hopes of the gas and Diesel engine makers, as far as municipal work is concerned, must at present be turned mainly towards the smaller stations, in which the new problems to be faced are not so great, on which there are more data available, and in which, in case of unsuccess, the capital loss will not be so serious. Diesel engines, in particular, have of late made remarkable progress, and it is certain that no one building a new generating station of moderate power is, at the present day, justified in neglecting the very serious consideration of them. We hardly think the large gas-engine can be said to have yet attained a similar position. In the mere matter of capital expenditure, for instance, there is not enough extended experience available for any generally accepted figures to be extant. In the two papers read at Brighton some estimated figures for gas plants were given. Mr. R. M. Carr, the chief electrical engineer of Leek, where there is a gas-driven station, and who was speaking in favour of that type, gave in his paper a curve of capital cost for plant and machinery which suggested that for a 2000-kw. station the expenditure per kilowatt installed would be about 22*l.* ; while Mr. H. L. Howard, the chief electrical engineer of Barking, which has a Diesel-engine station, gave a corresponding figure of 15*l.* for a 10,000-kw. station. These figures were obviously not strictly comparable, but Mr. Carr's curve suggested that the cost of gas plant is not going to greatly fall per kilowatt installed, after a capacity of above 1600

kilowatts has been reached, and in any case it is obvious that the difference between the figures is too great for them both to be right. The truth is, of course, that there is no right in the matter. Figures of this sort are based on assumptions, which there is not yet sufficiently extended experience to enable one to make correctly for a general case which must be held to represent the mean of a large number of special cases, every actual example being a special case.

THE INTERNATIONAL RUBBER EXHIBITION.

THE chief novelties in the machinery exhibits at the Rubber Exhibition, which will remain open at the Agricultural Hall, Islington, until this evening, July 14, were noticed in our issue of June 30. We will to-day deal, in the first instance, with the more chemical side of the rubber problems, its synthetic preparation, the reclamation of rubber, and rubber substitutes, and then describe some further machines—testing-machines in particular.

The exhibits of synthetic rubber are not of a kind to alarm rubber-planters. Artificial rubber may some day oust the natural product, as synthetic indigo is replacing the natural dye. So far, however, artificial rubber can hardly compete in price with the material which various kinds of plants furnish. The problem of the synthesis of rubber is generally understood to involve two tasks: the preparation of isoprene, and the conversion of isoprene into rubber. Isoprene is a colourless, very mobile liquid, highly volatile, and distinguished by a peculiar, unpleasant smell; the boiling point is 33.5 deg. Cent., and the density 0.67. Some isoprene is obtained when natural rubber is submitted to destructive distillation. That some distillation product of rubber, subsequently identified as isoprene, changed, when treated with hydrochloric acid, into a substance having all the essential qualities of caoutchouc, was observed by Bouchardat in the fifties, as we pointed out in an article on artificial rubber last year.* Isoprene still remains the material on which many distinguished chemists rely in their endeavours to prepare rubber. Isoprene has the formula C_5H_8, and the constitution $CH_2 = C - CH = CH_2$; it is also known as

$$CH_3$$

methyl divinyl. Under certain conditions it polymerises into a very tough and stable elastic solid, which is supposed to consist of an unknown number of double molecules of isoprene $(C_{10}H_{16})n$; whether this latter hydrocarbon forms an open chain, such as we have just indicated for isoprene, or a closed chain or ring compound, is still unsettled. [Polymerisation signifies that several equal molecules have united to a complex compound.] Now rubber undoubtedly contains a hydrocarbon of the above formula $(C_{10}H_{16})n$ as its most characteristic constituent, and the polymerisation of isoprene into this compound has certainly been effected in various ways. It is customary to call the resulting product, which looks very much like rubber, synthetic rubber, and to say that it must be rubber. That seems to be a very wide assumption. In the first instance we do not know the value of the n. Further, in the latex of the rubber tree the elastic substance is suspended in very small globules; the membranes of these globules contain proteins; resins and certain salts are likewise present; they remain in the rubber, and they may all be essential; that is to say, the peculiar properties of rubber need not depend alone upon the properties of the hydrocarbon. It is not quite immaterial what substance (acetic acid, mineral acids, carbon dioxide, and smoke) is used for coagulating the latex, and recent researches on the reclaiming of rubber tend to show that the different properties which the more or less vulcanised rubber assumes at different stages of these processes must partly be ascribed, not to chemical reactions in the ordinary sense, but to various degrees of polymerisation. Passing to the practical aspect of the problems, we should say that the purification of isoprene and its separation from other compounds which are produced at the same time, is very difficult, and that the conversion of the isoprene into rubber is very incomplete, again owing to the formation of other compounds.

The two exhibitors of synthetic rubber are the Caoutchouc Syndicate, Limited, of 14 to 16, Cockspur-street, S.W., and the Silberrad Research Laboratories, of Buckhurst Hill, Essex. Dr. A. Heinemann, of the Caoutchouc Syndicate, explains that he starts either from oil of turpentine (as most scientists have done, and as the Elberfelder Farbenfabriken do in their Fritz Hofmann process), or from some carbohydrate, starch, sugar, sawdust. The oil of turpentine is broken up by heat in contact with finely divided silver or copper at a comparatively low temperature; at a higher temperature diisoprene would form instead of isoprene. The starch is boiled with acids to yield laevulinic acid ($C_5H_8O_3$), which, distilled with phosphorus trisulphide or other sulphur compounds, or with flowers of sulphur, passes into thiotolene; the latter is reduced by hydrogen or water-gas to isoprene. The impure isoprene (density, 0.684) is heated with some additional substance up to 105 deg. Cent. at a pressure of from 5 to 8 atmospheres for several days. The liquid turns viscous, as the specimens exhibited show; when poured out it forms a sticky colourless mass, which darkens when slowly dried (for days), and changes more and more into something like sheet rubber. The additional substance just mentioned may be ozone or some albuminoid; when ozone is used, the heating is only carried to 40 deg. Cent.

Dr. Silberrad is more reticent. He does not state what is his raw material nor explain his process, but he shows a small piece of compact rubber and the intermediate products, and claims to be able to produce isoprene at about 8½d. per lb., while Dr. Heinemann would do it for less than half that money and hopes to supply rubber at something like 6d. per lb.—which figure probably refers to the cost of raw materials.

As long as rubber is not manufactured by the ton, the reclaiming and re-forming processes deserve full attention, which they will indeed retain. The reclaiming of waste rubber—*i.e.*, old vulcanised rubber—is done by chemical agents, which, it is generally asserted, remove part of the sulphur, if not all of it; the re-forming processes merely grind up the material, cleaned from grease, and compress the more or less soft particles. The mass is subsequently heated at or above vulcanising temperature, while the high pressure is kept on. Only soft waste is applicable for reclamation; hard rubber, ebonite, is ground up and is re-used merely as filling material, but its sulphur content probably helps to vulcanise the fresh rubber to which it is added. The reclaiming is effected by means of alkali or acid, or with the aid of heavy oils or resinous compounds, or of volatile sulphur solvents. Reclaiming processes were first introduced in the United States, where fifty large works are now in existence. Several of these works apply acid processes (Mitchel), against which the objection is sometimes raised that acid, even in traces, is apt to corrode the rubber in which it is left, or to change its degree of polymerisation, so that a subsequent treatment with alkali and with steam is required; oils are added to the product during rolling. The alkali process of Marks, introduced about 1900 by the North-Western Rubber Company, of Manchester, treats the rubber with moderately concentrated alkali (caustic soda, as a rule), under a pressure sufficient to destroy the textile fibre; traces of alkali are not so injurious to the rubber as acid.

The North-Western Rubber Company, which owns the largest works of this kind, at Litherland, Liverpool (general superintendent, Dr. J. Torrey), has a fine show of its products in the Exhibition. Alkaline processes are also used, we believe, by the Russian Prowodnik Company, of St. Petersburg, which is well represented by Messrs. J. Lang, of 37, Fenchurch-street, by the British Recovered Rubber Company, of Clayton, Manchester (established 1872), in their "Amazon" brands, and by the Rubber Regenerating Company, of Trafford Park, Manchester. The Premier Re-Forming Company, of Walthamstow, E., exhibit various products—buffers, tiles, screw-stoppers, and inner rubber tubes for tyres.

The solvent process of Messrs. Max Fränkel and Runge, of Spandau, near Berlin, deserves a detailed notice. It is due to Dr. P. Alexander, who explains the process with the aid of specimens taken from the various stages. The works were established ten years ago, and the process is recommended for materials, old tyres, &c., which contain much mineral and textile matter. The material is disintegrated and treated for several hours under pressure with certain hydrocarbons, which dissolve the vulcanised rubber as such; the mineral and textile matters are not attacked, and are allowed to settle. The viscous solution could be mixed with acetone or alcohol in order to precipitate the rubber and thus to separate it from the oils and other organic matter, &c.; the recovery of the solvent would be too difficult, however, and these substances are left in the solution, which, on distilling the solvent off, appears as a black or grey (according to the original colour) sticky mass, which is dried and then rolled into sheets. That this regenerated product is really rubber, though vulcanised, Dr. Alexander proves by the nitrosite reaction and other reactions. If the solution in hydrocarbon is treated with a little concentrated alkali, an "artificial latex" of vulcanised rubber results, which contains some alkali and will mix with water (the real latex does not), and which can be coagulated just like ordinary latex; the precipitate is gelatinous, however, and will redissolve in water. Dr. Alexander considers that the alkali effects a depolymerisation, and that changes in character which rubber undergoes during its manufacturing processes, which make it hard or plastic, according to temperature and other conditions, are partly due to successive polymerisations and depolymerisations. His regenerated rubber is of decidedly superior appearance, and can be worked into tubing, coils, &c., without any addition of fresh rubber (which is customary with most other processes, at least for certain purposes).

What science can achieve is shown by the United Malaysian Rubber Company, of Pinner's Hall, Austin Friars, E.C. Their raw material is rubber from the jelutong trees of Borneo; the stuff looks poor, and is crumbly like cheese, or very sticky and hardly elastic at all; yet a good rubber is produced from it, in addition to resin and resin oils. Rubber substitutes of all kinds, white amber, and dark products prepared from oil, as well as all kinds of mineral matters, are exhibited by Mr. Alfred Smith, of Clayton, Manchester, Messrs. Typke and King, of 16, Mincing-lane, and others.

The M.R., mineral rubber, exhibited by Messrs. Alden and Co., of Liverpool and London, and by the Canadian Mineral Rubber Company, of Toronto, Chicago, and 34, Nichols-lane, E.C. (Pioneer M.R.), is obtained from gilsonite, a brittle natural hydrocarbon occurring in Utah; the resulting product is soft, melts (or softens completely) at 280 deg. Fahr., and leaves no ashes. The Canadian Company has used it as a substitute for rubber and asphaltum since 1898. Recent antiseptic coagulants for rubber are exhibited by the Elias Pure Rubber Process Company, of 9 and 10, St. Mary-at-Hill, E.C., as a dry powder, which is dissolved in water, and by the Purub Company, of Berlin, S.W., 68. The "purub" is the invention of Dr. Sandmann, and consists essentially of hydrofluoric acid, which he originally used for preserving fruit; the acid is bound by the salts of the fruit or rubber and thus rendered harmless; $\frac{1}{16}$ oz. of the purub, which is supplied in lead bottles, is reckoned per gallon of latex.

Of special products we may mention the 20,000-volt gloves (seamless rubber, lined with sockinette) and boots for electricians, of the Harburg and Vienna India-Rubber Works, of Harburg-on-the-Elbe, and the "polarit" goods (for acid and oil works), the "polarit" jointing material for superheated steam, the imitation leather, and the solid tyres of Messrs. Polack, of Waltershausen, and of the Polack Tyre and Rubber Company, of 32, Basinghall-street, E.C.; one of their 5-ton lorries for the Great Central Railway had covered 25,814 miles and looked still in fair condition. In the tyres of Messrs. S. Herz, of Berlin, and of 15, Dowgate-hill, E.C., the fabric is woven to shape in one piece, which is saturated with rubber solution and applied in continuous layers without joints.

The Royal Prussian Materialprüfungsamt, of Gross Lichterfelde, near Berlin, display an interesting collection of their rubber-testing machinery in the German Section, one of the most instructive and comprehensive, though not the most attractive section of the Exhibition. In view of the importance which is attached to mechanical rubber-testing, Professor Martens, director of the Prüfungsamt, recently presented a memoir on the subject to the Prussian Academy of Sciences, in which he drew attention to a book on "Kautschuk und seine Prüfung," published by his colleagues, Hinrichsen and Memmler; copies of these publications are on view. Several of the machines have been built to the designs of Professors Martens and Dalén, by Mr.

* See ENGINEERING, May 13, 1910, page 617.

Louis Schopper, of Leipzig, whose stand adjoins that of the "Amt."

As it was found that rubber specimens of the shape of test-bars, with or without wider ends, which broke near the heads, where they were gripped, and also the 8-shaped samples (used in cement testing) were not suitable, Professor Dalén introduced cylindrical rings, 44.6 mm. internal diameter, and 6.4 mm. in thickness, for these tests. The rings are stamped out of sheets by special machines fitted with ring knives, or cut on the lathe; they are stretched over two rollers; the upper roller turns in ball-bearings, the lower is rotated by toothed gearing, so that the rubber ring travels while under test, and is evenly strained. The two rollers just mentioned are attached to the upper portion of a column apparatus, which stands on two feet set at an angle. In their general construction these machines resemble the renowned textile-testing machines of Mr. Schopper, which may be worked by hand, electric motor, or by hydraulic pressure. The rubber-testing machine in question is joined through a Martens valve to the water main; it requires a pressure of about 40 lb. to the square inch; the pressure forces the piston, to which the lower roller is fixed, down into the barrel which forms part of the stand. The stress is indicated by a lever moving over an arc which is provided with teeth on its inside; the lever is gripped at the moment that rupture takes place. The extent to which the rubber ring stretches (it may be ten times its diameter) is shown by a pointer moving over another arc. When the test is not carried to the breaking point, the permanent set which the ring has taken is measured on a simple small machine, in which the lower roller is under a constant load. The elongation depends, to a considerable extent, upon the vulcanisation, of course, and the "Amt" therefore has its own vulcanising plant. Vulcanised rods are apt to develop transverse cracks under load tests, and it is owing to these cracks that they do not stretch at a uniform rate, but periodically at an accelerated rate.

Fatigue tests are conducted, with four rings simultaneously in a horizontally-arranged machine, in which the stress is alternately increased and diminished, until the specimen gives way; the machine then stops and marks the number of stress applications. In another machine, a modification of a paper-testing machine, the strip or sheet of rubber is alternately pulled to right and left and folded over. In another machine, again, balls 30 mm. in diameter are run under a heavy load in a V-groove; this very characteristic test determines the wear of the rubber. Another machine serves a similar purpose; a rubber ring is suspended over a lower roller, against which an upper loaded roller is pressed; the pulleys revolve until the ring is worn through. The rubber rolls for typewriting machines are tested with the aid of an electro-magnetic hammer.

As regards strength tests of balloon fabrics, there is no generally-accepted practice so far. German military men would like to have sample strips 1 metre in width; others call for tests of part of the actual finished structure, with all its seams, &c., or demand bursting tests of especially prepared cylindrical specimens; these specimens are expensive, and a great deal would depend upon their finish. The Prüfungsamt prefers to use strips 50 mm. in width for the strength tests, and circular sheet samples for the bursting and most of the other tests. The discs are of areas of 0.01, 0.02, 0.03, 0.05, 0.1, 0.3 square metre, and are held by planed cast-iron clamps and rubber. Permeability and heat-transference tests are also made at the Prüfungsamt by apparatus due to Heyn and Bauer; in the latter the stretched sheets are exposed to radiations, and the temperature is determined in the space behind the sheets by means of thermo-couples.

We stated already that Mr. Louis Schopper, of Leipzig, represented in this country by Messrs. John Griffin and Sons, of Kingsway, W.C., shows his rubber-testing and also textile-testing machines; it is the only group exhibit of its kind in the Hall. Some apparatus, viscosimeters, and small centrifugal apparatus for rubber analysis, are also to be found on the stand of the chemical laboratories of Dr. R. Henriques's Successors, Dr. E. Marckwald and Dr. F. Frank, of Berlin, S.W., 68.

With regard to the rubber-washing machine of Messrs. Werner, Pfleiderer, and Perkins, of Peterborough, which was mentioned in our first notice, we should like to add that the machine does not turn out the rubber in the form of sheets, but in the form of a coarse-grained dough. The rolls are not keyed to the shaft, but cast on them, and are deeply corrugated; when in operation the two rolls of a machine remain at a fixed distance apart, and any particles of wood, pebbles, &c., in the rubber would not be splintered or broken, but squeezed into the slots and would drop out or be caught on the ledges. The two rolls carry the rubber down between them, round, and up again. The rolls exhibited by the Auto-Electric Vacuum Drying Syndicate, of 709, Salisbury House, Finsbury Circus, E.C., are supplied plain, fluted or grooved, solid, or chambered for heating, by Messrs. Bever, Dorling, and Co., of Bradford. The electric-vacuum drying-stoves of the firm consist of glass shelves heated by coils which are pushed over horizontal rods arranged between the shelves; the temperature is controlled by means of thermostats. The vacuum drying and evaporating apparatus of Mr. Emil Passburg, of Berlin, exhibited by Mr. James Livingston, of 30, Great St. Helens, E.C., are made stationary and rotary, and are heated with exhaust steam, gas, oil, or electricity.

The automatic rubber-thread-cutting machine of Messrs. J. and P. Hill, Ordnance Works, Sheffield, is provided with a disc knife which runs at 1500 revolutions per minute in a cast-iron case, into which water is forced. The rubber to be cut is carried on a drum of canary-wood wrapped with a shell of cheap rubber 0.5 in. in thickness, to cut into, over which the rubber sheeting is wound to a thickness of 2 in. The knife makes a cut and is then withdrawn and advanced, so as to cut strips from $\frac{1}{16}$ in. to $\frac{3}{4}$ in. in width. The drum can be run at 90, 150, and 210 revolutions.

A small novelty is the exhibit of the steel studs for rubber tyres of Messrs. Haedge and Richter, of Hanover, represented by Mr. A. C. Jacobs, of 11, Abercorn-place, Maida Vale, W.; the studs consist of specially hardened heads and one or several soft shanks, with washers of various shapes; a riveting-machine for these studs is also on view.

We reserve descriptions of some machines of the Harburg Eisen und Bronze Werke, A.-G., of Harburg-on-the-Elbe, an hydraulic autoclave for vulcanising tyres, &c., the four-piston pump for this autoclave (pressure up to 300 atmospheres), and a three-high calender.

The Exhibition is well stocked and arranged. International conferences of planters, manufacturers, chemists, &c., were held in connection with it during the first fortnight. The arrangements made for the conferences cannot be praised; excellent papers were read and discussed, but a preliminary programme was not issued, and sometimes the lecturers themselves did not know till the very morning when their turn would come.

THE WORKING OF THE BOILER EXPLOSIONS ACTS.

THE annual report for the year ended June 30, 1910, on the working of the Boiler Explosions Acts, 1882 and 1890, has just been issued by the Board of Trade. During the period named, 98 preliminary inquiries and 5 formal investigations were held under the provisions of the Acts. Of the 103 explosions thus dealt with, 43 resulted in loss of life or personal injury, 14 persons being killed and 62 injured. The 14 deaths were caused by 11 explosions, of which 4 occurred on land and 7 on ships.

For the previous 27 years the average number of explosions, and the average number of persons killed and injured, were 69.3, 27.1, and 57.9 respectively. It will therefore be seen that the number of explosions dealt with in the year under review again shows an increase above the average. The number of persons injured, however, is only slightly above the average, while the number of persons killed is only about one-half of the average for the period named. The report states: "It is so far satisfactory to note that the increase is not in the number of serious explosions, and there is reason to believe that during the past year a larger proportion of the minor explosions which occurred were brought to the notice of the Board of Trade than in previous years." In four out of the five cases in which formal investigations were held, the Courts found that persons who had been connected with the boilers were to blame for the explosions, and they made orders for the payment of costs in three of these cases, the total sum ordered to be paid amounting to 83*l*.

Of the 103 explosions reported on, 60 occurred on land, and 43 on board ship. By the former 4 deaths and 42 cases of personal injury, and by the latter 10 deaths and 20 cases of personal injury were caused. In 38 cases the boilers, &c., had been inspected or insured by Lloyd's underwriters, the Board of Trade, or marine insurance companies, and in 19 cases by boiler insurance or inspection companies or associations. In the 46 remaining cases the boilers, &c., were under no special system of inspection or insurance. Appendices B, C, and D, added to the report by Sir R. Ellis Cunliffe, Solicitor to the Board of Trade, give some further information. Appendix B gives the causes of the explosions as follow:—

Deterioration or corrosion	26
Defective design or undue working pressure	32
Water-hammer action	9
Defective workmanship, material, or construction...	16
Ignorance or neglect of attendants	8
Miscellaneous	12
	103

The 103 explosions are classified as having arisen from the following types of boilers, &c.:—

Horizontal multitubular	16
Vertical	6
Lancashire...	2
Locomotive	3
Water-tube	9
Tubes in steam-ovens	15
Heating apparatus	3
Steam-pipes, stop-valve chests, &c.	30
Miscellaneous	19
	103

Appendix C gives the following list of boilers, &c., which exploded, and regarding which formal investigations were conducted by the Board of Trade:—

Steam-chest	1
Vertical boilers	2
Locomotive boiler	1
Still	1

These explosions resulted in the death of three persons and injuries to ten others. The report adds: "The causes of these explosions have been clearly ascertained, and in no case has the explosion been attributable to unavoidable accident."

Appendix D, reproduced in the following table, gives the total number of explosions dealt with since the passing of the Acts, the number of lives lost, and the number of persons injured.

Year.	Number of Explosions.	Number of Lives Lost.	Number of Persons Injured.
1882-83	45	35	33
1883-84	41	18	62
1884-85	43	40	62
1885-86	57	33	79
1886-87	37	24	44
1887-88	61	31	52
1888-89	67	33	79
1889-90	77	21	76
1890 91	72	32	61
1891-92	88	23	82
1892-93	72	20	37
1893-94	104	24	54
1894-95	114	43	86
1895-96	79	25	48
1896-97	80	27	75
1897-98	84	37	46
1898-99	68	36	67
1899-1900	59	24	65
1900-1	72	33	60
1901-2	68	30	55
1902-3	69	22	67
1903-4	60	19	45
1904-5	57	14	40
1905-6	54	25	21
1906-7	77	28	65
1907-8	73	23	50
1908-9	93	12	53
1909-10	103	14	62
Totals ..	1974	746	1625
Average of 28 years ..	70.5	26.6	58.0

A large proportion of the explosions referred to in the report were of a very simple character, such as those arising from tubes in bakers' ovens, of which 15 cases are given. It is satisfactory to note that the number of serious explosions is by no means on the increase, and it is to be hoped that we are within appreciable distance of their practical extinction. The investigation by the Board of Trade of all accidents, whether serious or of a minor character, and the circulation of information respecting the causes and means of prevention, must tend to the attainment of greater security in working.

NOTES.

THE GREAT BALTIC MOTOR-BOAT RACE.

THE great international motor-boat race across the Baltic started from the Swedish naval port of Karlskrona on the evening of June 28, bound for the Island of Bornholm. Of the fourteen boats entered only seven put in an appearance at the start; the first boat was off at 8 o'clock, and the rest at two minutes' intervals. They were :— Bolinder VIII., Tatjana, Alba, Avance, Hermes, Penta IV., and White Horse. Two torpedo-boats accompanied the motor-boats as far as the Kalmar Sound; the course of the competing boats was round the Island of Bornholm and back to the Swedish port of Kalmar, which had to be touched, and from thence to the Varholm fortification in the Stockholm Skärgard. The weather was unsettled and the sea very rough. The Bolinder VIII., which started as No. 1, went ahead at such a speed that the torpedo-boats lost sight of her half-an-hour after they got into the open sea, Hermes being second. At 4.30 A.M., June 29, the Hammeren rock in Bornholm was sighted from one of the torpedo-boats (with the speed of which the heavy sea had seriously interfered), whilst the Hermes was 3 to 4 miles ahead. Bolinder VIII. sought shelter in an East Coast port in Bornholm; the Hermes passed Nerö (Bornholm) at 8 A.M., and was then carrying sails. The Tatjana collided with some floating timber and had to seek refuge at Bornholm. The Hermes reached Kalmar at 6.43 P.M. on June 29, starting at 7.23.30. Bolinder VIII. reached Kalmar at 6.49, on the same day, starting again at 7.34. The Avance reached Kalmar at 9.20.30, leaving again at 9.25. *En route* for Varholm the Bolinder VIII., however, easily beat the Hermes, arriving at the winning-post at 12.36.45 P.M. on the Friday. Her skipper, Lieutenant Isberg, had himself been at the wheel during the whole of the 40 hours' trip, with the exception of a couple of hours' rest. The crossing of the Baltic to Bornholm had been very rough, with fog and a strong westerly gale, the seas incessantly washing over the deck. The average speed had been rather more than 11 knots; the motor had worked very satisfactorily, and the boat, in spite of its long and narrow build, had behaved very well in the rough sea; sails had only been used for a short time. The Hermes reached Varholm at 3.38.40, and Avance at 6.34.14, its owner having ordered dinner to be ready by 6 o'clock. The Hermes was the only one of the competing boats which had gone direct round the Island of Borholm, and she had not taken in a single sea; sails had been used during the latter part of the trip, when the speed was 13 to 14 knots. The Avance, from Bornholm to Varholm, had not taken in a single wave on her deck. The other three boats (the Tatjana being disabled) had all sought shelter at Bornholm, starting again in a body at 9.15 P.M., Thursday, reaching Kalmar on Friday afternoon, Alba at 1.32, Penta at 2, and White Horse at 5.40. They were expected to reach Varholm on Saturday forenoon.

INSURANCE AGAINST NON-EMPLOYMENT IN FINLAND.

A special committee in Finland has just finished its labours and drawn up a proposal for insurance against non-employment—a matter which is at present to the fore in most countries. The Finnish proposal provides for the establishment of non-employment funds, from which aid can be rendered to the members in cases of need. Such funds may be formed for the whole country or for certain districts, and also for societies and unions of societies, provided that the funds in question are kept entirely apart from the other objects of the societies. Any labourer who complies with the regulations of the non-employment funds can become a member. Such funds, however, when formed within a society or a union, need only receive as members such men as are otherwise eligible. The limits as regards age are put at 18 and 60 years. The members can only belong to one non-employment fund subsidised with public money, and the subscriptions paid by members are to be so calculated that they, jointly with the State aid, will suffice to provide for the obligations of the fund. Non-payment of subscriptions within the prescribed time entails exclusion and forfeiture of payments already made. The non-employment funds can grant their members day money, house-rent, and travelling money. A member is not entitled to support unless he has been paying for six months and his non-employment exceeds six days, with fifteen days as a limit. The assistance must not exceed a maximum of two-thirds of the average pay of the member, though not less than 50 penni or more than 3 marks Finnish. Day money during twelve consecutive months must not exceed an aggregate of ninety days. Members who for three years have drawn the highest permissible support can receive no further aid until another twelve months has elapsed. The non-employment fund must not render aid to members who join in a strike, or to sick or disabled members, or to members who without proper cause have left work, or with proper cause have been discharged from work, or to members who, without the sanction of the fund-board, refuse to accept suitable work for which suitable payment is offered. The Imperial Senate, on being petitioned, will grant the non-employment funds a State subsidy of half the fund's management expenses and one third of the aid the fund has paid to its members who during the last two years have been resident in Finland. In case aid has been paid to a member in a place where there is a municipal bureau for finding work, the man shall show that the said bureau has been unable to find work for him during the time he has received aid. State aid is not to be paid to non-employment funds with fewer members than fifty. State aid can, under certain circumstances, be withdrawn.

UNPRECEDENTED ACTIVITY IN SHIPBUILDING.

Lloyd's return of vessels under construction in the United Kingdom shows that there are at present in various stages 560 vessels, the tonnage of which exceeds that at any previous period since such figures were collected by Lloyd's. The number and total of merchant ships is 496 vessels, of 1,476,394 tons, 102,000 tons more than at the beginning of April, and 358,000 tons more than a year ago. The previous record total, which was returned in September, 1901, was 62,000 tons less than at this time. The recovery from "bottom," touched in the autumn of 1908, has been exceedingly rapid. For some time in 1908-09 the total merchant tonnage in progress fluctuated between about 730,000 and 900,000 tons. The upward movement began in September, 1909, and, with the exception of a slight check at the end of 1910, due to the lock-out, it has continued since, the recovery in twenty-four months being from 750,000 tons to 1,450,000 tons. When to this is added the tonnage of warships in course of construction the total becomes still more remarkable, being 1,891,934 tons This total is 922,000 tons more than was the case in July, 1909, while the improvement, as compared with a year ago, is nearly 400,000 tons. The figures are made up as follow :—

	July, 1911.	July, 1910.	July, 1909.
	tons	tons	tons
Merchant steamers ..	1,466,989	1,115,484	739,991
Merchant sailing ships ..	9,405	3,103	5,714
Total merchant ships ..	1,476,394	1,118,587	745,705
H.M. ships in dockyards ..	111,140	96,080	84,370
H.M. ships in private yards	271,350	239,193	89,980
Foreign warships	33,050	43,250	49,600
Total	1,891,934	1,497,110	969,655

While practically all districts have profited, the greater increases, so far as merchant work is concerned, are recorded for the Clyde, Tyne, and Wear. Barrow, however, is mostly concerned with warship work, and a very considerable proportion of it is credited to that port. The Liverpool total of merchant ships is much less owing to the completion of the large contract for refrigerator ships for Nelson's Line, but the laying down of the battleship Audacious more than compensates for the falling-off in merchant work. At Glasgow there are 103 vessels, of 332,892 tons, in course of construction. This is nearly 50,000 tons more than three months ago, and 104,000 tons more than a year ago. In the case of Greenock the improvement is almost as great, for the fifty-eight vessels, of 241,770 tons, now building represent 19,000 tons more than three months ago and 61,000 tons more than a year ago. On the Tyne the total is 5000 tons greater than in April last, and 52,000 tons more than in June, 1910, there being 67 vessels now on the stocks, making up a total of 246,504 tons. At Sunderland there are 54 vessels, of 195,104 tons, in progress; this is 38,300 tons more than three months ago, and 87,000 tons more than twelve months ago. Middlesbrough, however, has not fared so well, the total being 10,000 tons and 16,000 tons higher than in March last and in July of last year respectively. Fifty-one vessels are being built, and these make up 86,649 tons. The condition at Hartlepool has not changed much in the past few months; the addition, as compared with July of last year, is only between 4000 and 5000 tons. The number of vessels being built is 17, with a collective tonnage of 69,506 tons. These figures for the respective districts do not include the warship work, and it may be said that not for many years have so many large fighting ships been in course of construction. There are in all 12 ranging from 22,500 to 26,500 tons, the latter being the displacement tonnage of the cruiser Queen Mary, building at Palmer's works at Jarrow-on-Tyne.

THE GROSVENOR-ROAD PUMPING-STATION OF THE LONDON HYDRAULIC POWER COMPANY.

ON Wednesday, the 12th inst., at the invitation of the chairman and directors, an opportunity was afforded of inspecting the London Hydraulic Power Company's new pumping-station in the Grosvenor-road, S.W. This station is very complete and well laid out, and includes a river frontage, though the site is intersected by the Grosvenor-road. The whole of the station, with the exception of the coal-unloading wharf, is, in fact, on the side of the road remote from the river. At present the plant includes five engines, each capable of delivering at the rate of about 28,000 gallons per minute, at a pressure of 800 lb. per square inch, together, of course, with the necessary boilers and accessory plant. Nearest to Grosvenor-road stands the coal-store, and next to this comes the boiler-house. Contiguous to the boiler-house stands the engine-house, and beyond this the settling-basins. The latter consist of six reservoirs of an aggregate capacity of 2¼ million gallons. They are approximately 100 ft. by 38 ft., and are constructed on the Hennebique ferro-concrete system. The compartments are filled from the river by 20-in. pipes, laid at about half-tide level. Wash-out pipes, 14 in. in diameter, are laid below the bottom of the reservoirs, and are used to carry away the sediment after each emptying.

After time has been allowed for settlement, the water is drawn off by the circulating pumps on the main engines, passed through the condensers, and delivered to an unfiltered-water tank above the coal-store. From this tank the water is passed through spherical filters of the Pulsometer Engineering Company. There are sixteen of these filters, situated in two rows of eight, over the coal-store, but below the unfiltered-water tank, from which the water is fed to the filters by gravity. Of the sixteen filters two are kept as stand-bys, and one of the remainder is always being cleaned. The filtering medium is crushed quartz. Each filter can deal with 4500 gallons per hour. Hydraulic blowers are used for cleaning them. From the filters the water passes by gravity into a filtered-water tank over the boiler-house. Both the filtered and unfiltered-water tanks have a capacity of 300,000 gallons. They are built of cast-iron plates, with stringers, &c.

The main engines are of the triple-expansion surface-condensing inverted direct-pumping type, working at a steam pressure of 180 lb. per square inch. From the main engine-pumps the water passes to two accumulators, of which the ram crossheads carry about 150 tons load. In the engine-house are also two auxiliary vertical direct-acting pumps for supplementing the engine circulating-pumps in delivering water to the unfiltered-water tank. A recorder, by Messrs. W. H. Bailey and Co., Limited, also in the engine-house, records automatically the speed of the engines. Outside the boiler-house is a water-softener, on the Desrumaux system, capable of dealing with 1000 gallons per hour. The feed-water, after passing through filters, is measured by "Lea" recorders. At present there are four Babcock and Wilcox water-tube boilers installed, each capable of evaporating 6000 lb. of water per hour at 180 lb. to 200 lb. pressure, and superheating to 100deg. to 120deg. Fahr. The boilers are fitted with chain-grate stokers with hopper feed, the stokers being driven by Pelton motors. Two economisers are arranged in the flue, the scraper gear for these being driven by hydraulic motor. There are two hydraulic direct-acting horizontal feed-pumps for supplying the boilers, each capable of delivering 2000 gallons of water per hour against boiler pressure.

The coal-store is arranged for a capacity of 1000 tons in six compartments. Coal is conveyed to it from the wharf by a conveyor running under the Grosvenor-road, and from it to the boiler-house, also by conveyor. Coal can, in fact, be taken direct to the hoppers over the boilers or discharged into one of the six compartments of the store and conveyed thence subsequently

to the boilers by a conveyor. The ashes from the boilers are likewise handled mechanically and discharged at the wharf either into wagons or barges, passing on the way under the Grosvenor-road. The plant at the wharf includes an hydraulic coaling-crane with a grab bucket discharging into a hopper to which is fitted an automatic coal-weigher with both indicating and recording gear. The intakes and the discharge of the wash-out pipes are in front of the wharf, and the pipes pass thence to the reservoirs along a large subway and pipe-trench.

In the whole station, steam is used only in the main engines; all other plant is hydraulically driven. The drainage from the boiler-house is lifted from a sump to the sewer intercepting-chamber by two automatic hydraulic ejectors. The station supplies three distribution mains, two of 8-in. bore and one of 6-in. bore, automatic control-valves being placed in the subway to isolate the system in case of accident.

During Wednesday afternoon demonstrations were given of two interesting applications of hydraulic power. One of these consisted of an adaptation of this form of power to vacuum cleaning. With an exceedingly simple fitting a vacuum of 30 in. can be almost instantaneously produced, but it is found best to work with one not exceeding 25 in., in order to keep the pipes dry. At this vacuum the dust is drawn up through thick carpets, so that the covering and floor are both cleaned, and the dust is immediately disposed of down the waste-pipe. We understand that many large business houses and places of entertainment now employ this system. The second application of which a demonstration was given was of its use for fire service. By means of an hydraulic injector, working in conjunction with a tank supply, a jet at about 75 lb. pressure, capable of reaching to a height of about 120 ft., can be produced.

In addition to the workshop in which the tools are driven by a Pelton motor, and to the engineering features of the station above described, there are well-arranged stores, offices, and mess-room. The station gives one the impression of being well arranged, though the site must have been no easy one to deal with. The main engines and hydraulic plant are by the Hydraulic Engineering Company, Limited, Chester.

A CRUISER FOR THE TRAINING OF CHINESE OFFICERS.

MESSRS. VICKERS, LIMITED, launch to-day (Friday) from their Naval Construction Works, Barrow-in-Furness, a cruiser named Ying-Swei, for the Chinese Navy, for the training of officers and men in connection with modern munitions of naval warfare, and therefore a forerunner of that new navy which will be built within the next few years for China.

While having all the fighting capacity possible in a ship of the draught (13 ft.) and of the limited displacement (2400 tons) prescribed by the Chinese authorities to meet certain harbour conditions, she excels in the comprehensive character of the provisions introduced for training purposes. Messrs. Vickers, Limited, are responsible for the design, which, like the plans for many of the later warships built by the company, have been prepared by Mr. T. G. Owens, the naval constructor and a director of the company. The special features of the design are:—(1) The great variety in the size of the guns fitted—6-in., 4-in., 14-pounders, 3-pounders, and 1¼-pounders—all introduced primarily for instructional purposes; but incidentally making the cruiser a formidable fighting ship. (2) The different types of boilers on board—cylindrical and water-tube—so that the Chinese stokers may acquire experience. (3) The adoption of alternative systems of auxiliary machinery as far as is consistent with efficiency, for the education of Chinese officers and crew. (4) The unusually large quantity of ammunition carried; 160 rounds for each of the two 6-in. guns, 200 rounds for each of the four 4-in. guns, and 1000 rounds for each of the smaller guns, which permits of extensive battle practice, and confers the advantage of the maintenance of a long engagement in war. (5) The embodying of an unusually thick protective deck—1½ in.—in such a light cruiser. (6) The ensurance of a speed of 20 knots under easy steaming conditions and without exacting that care and organisation in the stokehold which come only with prolonged experience. The principal dimensions of the ship are as follow:—

Length between perpendiculars ...	330 ft.
Breadth, moulded	39 ft. 6 in.
Depth ,, ...	23 ft. 9 in.
Mean draught	13 ft.
Displacement (about)	2500 tons
Speed (about)	20 knots

The armament consists of two 6-in. quick-firing guns, one carried on the forecastle deck, and the other on the poop deck; four 4-in. quick-firing guns, placed on the upper deck—two at the aft end of the forecastle, and two at the fore end of the poop, at the sides of the ship; two 14-pounder quick-firing guns—one on each end of the upper deck amidships; six 3-pounder quick-firing guns—three carried on each side of the upper deck in the waist, and two 1¼-pounder quick-firing guns placed on the bridge. Two-18-in. revolving deck torpedo-tubes are carried, one on each side of the upper deck aft. The guns and torpedo-tubes are controlled in accordance with the latest practice. Accommodation is provided for 230 officers and men and 40 cadets.

The propelling machinery is of the Parsons turbine type, with three lines of shafting, and one propeller on each shaft. The turbines are arranged in one engine-room. The high-pressure ahead turbine is on the centre shaft, and a low-pressure ahead on each wing shaft. The wing shafts are arranged for working astern, a reversing turbine being incorporated in each of the two low-pressure turbine-casings.

NOTES FROM THE UNITED STATES.

PHILADELPHIA, July 5.

THE low prices prevailing for coke have finally started furnace and foundry companies to heavy buying. Contracts were placed last week for several months' output, covering deliveries to the end of the current year, the later buyers having to agree to a 10 cents per ton advance. The curtailment of production since April 15 prevented any accumulation of stocks, and this assisted makers in advancing prices. One Pittsburg concern contracted for 9000 tons per month for six months; another furnace company took 50,000 tons for July and August delivery, and 50,000 tons for delivery after September 1. All other coke-consuming interests are in the market this week, making themselves safe. A great many idle ovens will soon be started up.

The car-builders are in sight of much new business. Inquiries have been received within the past few days for 12,000 cars from the trunk lines, exclusive of passenger coaches, of which 800 are for the National Railways of Mexico. Several systems have presented inquiries for rails during the past few days. The inquiries cover a little over 100,000 tons. This sudden improvement in demand has stimulated confidence in further progress. Prices, which have been weakening, have developed a stronger tone. The weak factor in the situation continues to be the large volume of idle capacity. On the other hand, the strong factor is the urgent necessities for iron and steel construction material, which are becoming more and more urgent. Tariff possibilities are pretty well discounted. Reciprocity discussions have lost interest, and threaten to wind up as a political issue; but it will be a losing one, as the general sentiment of the people is in favour of it, and of the extension of the principle to other countries if conditions ever become favourable.

THE ROAD BOARD'S EXPERIMENTS IN KENT.

UNDER the able direction of Mr. H. P. Maybury, M. Inst. C.E., the county of Kent has in recent years become nearly as famous for the efforts made to adapt its roads to modern traffic requirements as it has long been for the charm of its landscapes. Whilst in other portions of the kingdom the advent of the motor-car, and the consequent impossibility of ignoring longer the bad condition and construction of most of our highways, merely led to violent protests against the car and its users, in Kent steps were quickly taken to discover effective methods of combating the nuisance resulting from the simultaneous use on the roadways of "percussive" traction, such as that of draught animals, and of mechanically-propelled vehicles fitted with soft tyres. The debt which road surveyors have thus incurred to Mr. Maybury and his progressive county council is now about to be further increased, since, with the assistance of the Road Board, arrangements have now been completed for a comparative test, under practically identical conditions, of most of the improved methods of road construction so far introduced.

The stretch of road selected for the test is a 1½-mile section between New Eltham and Sidcup, on the London-to-Maidstone road. The recorded traffic along this stretch of road is very heavy, being about 180,000 tons per yard of width per annum, or 500 tons per yard width per day of 24 hours. In a 14-day census 4516 motor vehicles passed over the road, and 6361 horse-drawn ones. Included in the motor vehicles were 22 traction-engines, which hauled 44 trailers, 1829 motor-cars and vans, 1468 motor-omnibuses, 122 steel-tyred motor-lorries, and 236 motor-lorries with rubber tyres. The stretch of road selected is slightly undulating, and is unshaded by trees save in one or two places. In all 23 kinds of road-surfaces are to be tested, each of which will be laid on an area of 1000 to 1200 square yards.

Sockets are to be fixed in groups of three across each section, which will serve as reference marks for testing the rate of wear. The Road Board have appointed Mr. F. W. Greig, of 20, Alma-road, Sidcup, to act as resident engineer during the progress of the test, which will, of necessity, extend over some years. The twenty-three materials to be laid are:—(1) Ordinary water-bound granite macadam, laid by the Kent County Council. (2) The same, painted with tar. (3) Single "pitch-grouted" macadam, laid by the Kent County Council to the Road Board's Specification No. 3. (4) Double pitch-grouted macadam, laid to the Road Board's Specification No. 4. (5) "Durax" armoured paving, laid by the "Durax" Dustless Roads, Limited, of 20, Victoria-street, S.W. This consists of granite cubes grouted with coal-tar pitch tempered with creosote or tar, to which is afterwards added 30 per cent. of fine dried sand. (6) Granite macadam, laid by "Plascom" (1909), Limited, of Fawdry-street, Wolverhampton, with a binder of a bituminous character. (7) "Cormastik," laid by the British Cork Asphalt Company, Limited, of 85, London Wall, E.C. "Cormastik" consists of a mixture of granite or basalt chippings with sharp Thames sand, powdered Sicilian rock asphalt and Portland cement, with a binding of Cuban natural asphalt. (8) Tar-macadam, laid by Messrs. Chittenden and Simmons, Limited, the aggregate consisting of Kentish rag, with prepared tar and pitch as the binding medium, the two being mixed hot in a rotary mixer. (9) and (10) Tar-slag macadam, laid by Messrs. Constable, Hart, and Co., Limited, Clarence House, London, E.C. (11) "Tarmac," laid by Tarmac, Limited, of Etlingshall, Wolverhampton. (12) "Roadoleum" asphalt, laid by Mr. W. H. Stansbury, of 37, Moorfields, Liverpool; in this case the aggregate is Penmaenmaur diabase, broken to sizes between 1¾ in. and ⅜ in. The binder is a pure bituminous asphalt marketed by the Anglo-American Oil Company. (13) "Rocmac," laid by Rocmac, Limited, of Central Bank Chambers, Leeds; this consists of the usual Kent County Council aggregate, with "silicate-saccharate-carbonate" as the binding material. (14) Tar-macadam, laid by the Taroads Syndicate, Limited, of 9, Victoria-street, S.W. (15) and (16) Tarmacadam, laid by Messrs. Bristowe and Co., Limited, of 20, Tothill-street, S.W. (17) "Roadamant," laid by the Roadamant Company, Limited, 65, London Wall, E.C. Roadamant consists of refined Trinidad bitumen, natural rock asphalt, stone chippings, and the "roadamant" mixture. (18) "Lithomac" asphalt paving, laid by the Limmer Asphalt Paving Company, Limited, of Caxton House, S.W. This paving consists of crushed granite, sharp sand, and pure limestone, blended with bitumen. (19) "Pitchmac," laid by the Taroads Syndicate, Limited, of 9, Victoria-street, S.W. This is pitch grouted macadam. (20) Natural asphalt matrix, laid by the Val de Travers Asphalt Paving Company, Limited, Hamilton House, London, E.C. This consists of the Kent County Council aggregate, with a binder consisting of Trinidad Lake bitumen, and the natural rock asphalt. (21) "Asphalt macadam," laid by the Val de Travers Asphalt Paving Company, and consisting of natural rock asphalt broken into rectangular pieces and laid without any addition. (22) Trinidad asphalt macadam (3 in. thick), laid by the Trinidad Lake Asphalt Paving Company, Limited, of Townmead-road, London, S.W. In this case the aggregate consists of Channel Island granite bonded with prepared Trinidad Lake bitumen. (23) Trinidad asphalt macadam (4 in. thick), laid by the firm already mentioned. The contract cost of construction per square yard varies from 1s. 9d. up to 7s. 6d., the cheapest being, of course, ordinary water-bound macadam. Tarring the surface costs 1½d. per square yard. The contractors, however, in the case of some of the more costly systems of road construction give free maintenance for several years, whilst others claim that the cost of maintenance is very small. Taking this into account, the total cost of the improved pavements at the end of six years ranges from 9d. up to 19.5d. per square yard; but, so far as the higher figures are concerned, the contractors are in some cases prepared to maintain the surface free for ten years.

The data obtained in this series of experiments should prove of the greatest value, but, unfortunately, some years must elapse before a fair comparison can be made between the competing systems. It would be an immense advantage were any short-time method available for adequately testing them in the laboratory, but the attempt to find a solution to the problem of devising such tests seems hopeless.

THE GERMAN WIRE INDUSTRY.—The convention between German manufacturers of wire and kindred goods, the formation of which was beset by many difficulties, has collapsed, and ceased its functions at the end of June, the members being now free to contract for sales for delivery. This result is regretted by many of its members, as the convention worked fairly satisfactory. The stumbling-block in the way of a renewal of the union was the absolute refusal of several works to submit to any limitation as to production. This, on the other hand, was insisted upon, as far as the large manufacturers were concerned, as a mere price agreement handicaps certain works. Of late there had also been certain price reductions which were at variance with the agreement. The cessation of the convention will probably have an unfavourable effect upon the works which make wire rods.

DOCTORS AND THE MOTOR-CAR.—The motor-car has proved of the greatest utility to medical men, making possible a large increase in radius, as well as considerably augmenting the amount of work possible in a given time, but it is a first essential that the cars should be not only reliable, but easily repaired. Fortunately some cars are now so simple in their construction that the doctors find the work of overhauling and repairing them an enjoyable recreation. We have recently had a report from a practitioner who has himself driven a Wolseley car for close on 50,000 miles, and has just had a motor dismantled. It was the first time that the cylinder had been taken out, and it was found that the deposit on the piston-head was trifling (less than 1 oz.) and that there was scarcely any on the cylinder-head. The piston-rings were all bright, and so were the exhaust-valves, although they had never been ground in, and there was no pitting. There was a little lateral play at both ends of the connecting-rods, but no up-and-down play.

ST. PAUL'S BRIDGE.

TO THE EDITOR OF ENGINEERING.

SIR,—Presuming that the Committee will deal with the question in an exhaustive manner, within their reference, at least, may I mention one or two points on which a pronouncement would be acceptable.

They refer to the high-level character of the proposed bridge. Would not the proposed viaduct over Queen Victoria-street mean the spoiling of one beautiful new street in the making of another?

And, in view of the probability of thoroughfares on the foreshores (the north particularly), between London Bridge and Blackfriars Bridge, would not a co-ordinating alternative be preferable to a repetition of the awkward arrangement on the Embankment at Waterloo Bridge?

In the event of the former, Is an arrangement not possible whereby the existing Southwark Bridge might be dispensed with? and would not the appearance of the river be improved by its removal?

The latter queries refer to a contingency which ought to be taken account of. Reference to it also bears out the force of the contention expressed in your columns last week, that the whole question ought to be viewed in a much wider aspect and delayed to fit in with a larger scheme.

Yours truly,
O.B.I.T.

London, July 10, 1911.

THE EDUCATION AND TRAINING OF ENGINEERS.

TO THE EDITOR OF ENGINEERING.

SIR,—In the report of the discussion at the Conference on the Education and Training of Engineers, which appeared in your journal of the 30th ult., your reporter, in condensing my remarks on specialised entrance examinations, rather missed the point which I endeavoured to bring out, and that is, a boy who passes from a secondary school to an engineering college, and who after a time prepares to matriculate and work for a degree at the London University, ordinarily goes through a very disconnected course in mathematics, for at the secondary school he, in most cases, is taught *pure* mathematics, then at the college *practical* mathematics, and when he commences to prepare for his university examinations he has to again take up pure mathematics. In other words, this is a most wasteful sandwich system, as the change-over in the college from practical to pure invariably leads to his general work receiving a serious set-back; and, no doubt, this has not a little to do with the smallness of the proportion of university matriculated students there are in the leading colleges of the London district. The only satisfactory way I can see of straightening out this unfortunate condition of things is to get the authorities of the secondary schools to arrange for boys who intend to become engineers to receive instruction in *practical* mathematics during, say, the two years before leaving; and, at the other end, to arrange for a further continuity of study by inducing the university authorities to allow engineering students to matriculate and graduate without being obliged to sit in *pure* mathematics; for most engineering colleges have for years wisely realised that mathematics, instead of being an abstract discipline, should become the means of applying truths to the every-day affairs of the world we live in. As to the range of this work, it is safe to say that the excellent syllabus of the Board of Education in practical mathematics covers all the mathematics the engineer is likely to require in ordinary practice.

Yours truly,
HENRY SPOONER.

The Polytechnic, Regent-street, July 12, 1911.

TO THE EDITOR OF ENGINEERING.

SIR,—Recent speakers on the subject of the training of engineers have developed quite a habit of uttering warnings against specialisation; in one instance holding up as an example to be avoided the case of a modern university which has advanced so far as to give a degree in motor-car engineering and to appoint a professor in this subject. The standing of the speakers gives their utterances great weight, and at first sight it would appear that this university is moving on wrong lines; but further consideration shows that these warnings may be quite unnecessary; may, in fact, exert a harmful influence in helping to continue that type of education which produces the bookish-engineering graduate scorned by the practical man.

There is some confusion in the use of the word "specialisation" in this connection. The study of some limited field of engineering knowledge—for example, the heat treatment of metals—is specialisation; and the student would be well advised not to follow such a course to the exclusion of other studies. But the study of some one branch of engineering is not specialisation in this sense; it may be better termed "selection." Such specialisation or selection is to be strongly advocated as sound, educationally and economically.

The student generally devotes the first two years of his college course to the study of mathematics and the fundamental laws of chemistry and physics; afterwards he studies their applications to the problems of engineering under such groupings as strength of materials, heat engines, &c. There is danger here that the student may become a mere theorist, for the teacher unconsciously tends to teach his subject as a subject complete within itself, withdrawing more and more from actual practice as introducing difficulties foreign to his subject. The laboratory work becomes unreal, exercises are so arranged as to illustrate some particular point, and in the end, to take an example, the student may come to think that the theory of heat engines is a series of beautiful abstractions, but has little to do with the actual steam or petrol engine.

If, instead of studying engineering principles in general, the student concentrates on some particular branch, he at once becomes conscious of the need of general and systematic information. The effect is to broaden the field of study and yet to simplify, because the necessity and interdependence of each branch of study is realised. If motor-car engineering is selected, the principles studied, as strength of materials, become of some importance; the student begins to appreciate his ignorance of chemistry and the properties of gases and fluids; he feels the influence of modern developments in steels and alloys. He realises to what extent his theory of heat engines affects design as compared with popular demand, price, and other factors. In short, concentration has broadened his outlook and unified his knowledge. Economically the necessity of concentration is great. The idea that the student leaves college equally ready to take work in a shipyard, tool-room, or on irrigation work, assumes the existence of employers with the willingness and leisure to teach the beginners. This is a mistake. The student will have to teach himself, and his work will be the easier to the extent he has already prepared himself.

Yours truly,
W. MORGAN.

LAUNCH OF SPECIAL-TYPE DESTROYER.—H.M.S. Acheron, a torpedo-boat destroyer of the special type included in the 1910-1911 programme, and built to the design of Messrs. John I. Thornycroft and Company, Limited, was launched recently from this firm's Woolston Works, Southampton. The following are the particulars of the vessel:—Length, 251 ft. 9 in. between perpendiculars; breadth, 26 ft. 4 in. The propelling machinery consists of a twin set of turbines of the Parsons type, designed to give a speed of 29 knots, steam being supplied by three large water-tube boilers fired by oil fuel. The armament consists of two 4 in. and two 12-pounder guns, and the vessel also carries two torpedo tubes. It is noteworthy that this is the first to be launched of the six special destroyers ordered in the Admiralty programme of last year, and the vessel is also the first destroyer to be fitted with a two-shaft arrangement of turbine machinery. Messrs. Thornycroft have a sister vessel, H.M.S. Ariel, on the stocks, which is also in a forward state of completion, and will be ready for launching very shortly.

THE UNITED STATES BATTLESHIP "UTAH."—The battleship Utah, built for the United States Navy by the New York Shipbuilding Company at Camden, New Jersey, and fitted with Parsons turbines, has just completed her speed trials with satisfactory results. The vessel is 510 ft. long, 88¼ ft. beam, and at 28½ ft. draught displaces 21,825 tons. Her armament includes ten 12-in. and sixteen 5-in. guns, besides smaller machine-guns. The designed horse-power of the main turbines was 28,000 shaft horse-power, and this, it was anticipated, would give a speed of 20¾ knots. The measured-mile progressive speed tests included twenty runs in all over the measured distance of the Rocklands course—three runs at 10 knots, 12 knots, 19 knots, and 20¾ knots, with five at the highest possible speed, followed by three at 16½ knots. The actual speeds on these progressive runs were 10.556 knots, 12.015 knots, 19.049 knots, 21.228 knots, and 16.799 knots. The full speed was thus 21.228 knots, and was attained with the turbines running at 309 revolutions per minute, and developing 28,477 shaft horse-power. The Utah is practically finished, only 1.6 per cent. of the work remaining to be done, and she will probably go into commission about August 16.

PERSONAL.—The business of "Acer," Limited, cylinder-grinding specialists, of Hanwell, has been transferred to larger and more suitable premises at Leaborne Works, Harrow. The company has recently prepared for distribution a revised price-list.—The Electric and Ordnance Accessories Company, Limited, Cheston-road, Aston, Birmingham, is now represented, so far as its electric manufactures are concerned, in and round the city of Sheffield, for a radius of 10 miles, by Mr. H. E. Ridley, 104, Marlcliffe-road, Sheffield. The agency for the Vickers centrifugal fans will remain, as before, in the hands of Mr. J. Crawford, Manchester.—Messrs. Jno. Hy. Andrew and Co., Limited, Toledo Steel Works, Sheffield, have appointed Messrs. Bernard Holland and Co, 17, Victoria-street, S.W., to act for them in London and district, so far as the British Government Departments, railway companies, engineers, shipbuilders, contractors, &c., are concerned, the arrangement hitherto existing between Messrs. Campbell, Macmaster, and Co., 11 and 12, Clements-lane, E.C., and themselves having expired.—It is publicly announced that, in consequence of the death of the late Sir John Aird, the businesses of Messrs. John Aird and Sons and the Westminster Construction Company, Limited (of which the late Sir John Aird was chairman from its formation in 1899), have been amalgamated, and will in future be carried on under the registered style and title of "Airds, Limited." There will be little change in the management or staff. The chairman of Airds, Limited, is the present Sir John Aird, and the managing director Mr. Malcolm R. Aird.—We are informed by Messrs. J. Wardell and Co, manufacturing agents and merchants, that, on the 12th inst., they removed their offices to Westminster Chambers—namely No. 3, Victoria-street, Westminster, S.W. Their telephone number and telegraphic address will be as before.—Messrs. John Williams and Co., iron and steel manufacturers, Wishaw, Scotland, have appointed Mr. H. B. Sparrow, 65, Fenchurch-street, E.C., their sole agent in London.

NOTES FROM THE NORTH.

GLASGOW, Wednesday.

Glasgow Pig-Iron Market.—Last Thursday morning the pig-iron market was firm, but quite idle. Quotations for Cleveland warrants were nominally higher at 46s. 5d. cash, 46s. 8d. one month, and 47s. 1½d. three months sellers. In the afternoon a good tone again prevailed, and 3000 tons of Cleveland warrants were done at 46s. 5d. and 46s. 6d. cash, 46s. 7½d. one month, and from 47s. 1½d. to 47s. 2½d. three months. At the close sellers quoted 46s. 6d. cash, 46s. 9d. one month, and 47s. 2½d. three months. On Friday morning the market was quiet but strong, and Cleveland warrants improved in value. The turnover was 2500 tons at 46s. 7d. cash and 46s. 10d. one month, and closing sellers' prices were 46s. 7½d. cash, 46s. 10½d. one month, and 47s. 4½d. three months. Buyers of hematite offered 60s. 10½d. cash and 61s. 9d. three months, and sellers quoted 62s. three months. In the afternoon Cleveland warrants continued to improve, and 2000 tons changed hands at 46s. 11½d. and 47s. one month, and at the close the quotations were 46s. 9½d. cash, 47s. one month, and 47s. 6d. three months sellers. On Monday morning the tone was strong, and 3000 tons of Cleveland warrants were dealt in at 47s. and 47s. 1d. cash, 47s. 1d. fourteen days, and 47s. 1½d. eleven days. Closing prices were up to 47s. 0½d. cash, 47s. 3½d. one month, and 47s. 9d. three months. Hematite was also strong, and 2000 tons changed hands at 61s. 3d. and 61s. 2d. cash, and 62s. three months. The cash closing quotation was 61s. 3d. sellers and 61s. 1d. buyers. In the afternoon the market maintained its good tone, and 2500 tons of Cleveland warrants were done at 47s. 0½d. cash, and 47s. 9d. three months. At the close there were sellers at 47s. 1d. cash, 47s. 4d. one month, and 47s. 9½d. three months. Hematite was firm, and 500 tons were dealt in at 62s. 2d. three months, with sellers over, and buyers at 62s. 1d. For the cash position buyers offered 61s. 2d., and sellers quoted 61s. 3d. On Tuesday morning prices fell away a little, and the dealings consisted of 2000 tons of Cleveland warrants at 47s. and 46s. 10½d. cash, and 47s. 2d. and 47s. 1½d. one month. Closing sellers quoted 46s. 11d. cash, 47s. 2d. one month, and 47s. 8d. three months. An easier tone again prevailed in the afternoon, when Cleveland warrants to the amount of 7500 tons were put through at from 46s. 10d. to 46s. 8½d. to 46s. 9d. cash, and at 47s. one month. Sellers' closing quotations were down to 46s. 9d. cash, 47s. one month, and 47s. 6d. three months. When the market opened to-day (Wednesday), the tone improved, and 1500 tons of Cleveland warrants were put through at 46s. 11d. cash, 47s. 2d. and 47s. 1½d. one month. At the close there were sellers at 46s. 11d. cash, 47s. 2d. one month, and 47s. 7½d. three months. In the afternoon the market was firm, and Cleveland warrants were the turn harder. The turnover amounted to 3000 tons at 47s. twelve days, 47s. 3d. August 23, and 47s. 8d. three months, and closing sellers quoted 46s. 11d. cash, 47s. 2½d. one month, and 47s. 8d. three months. Cash sellers of hematite quoted 61s. 6d. The following are the market quotations for makers' (No. 1) iron:—Clyde, 60s. 6d.; Calder and Gartsherrie, 61s.; Summerlee, 63s.; Langloan, 63s. 6d.; and Coltness, 82s. 6d. (all shipped at Glasgow); Glengarnock (at Ardrossan), 64s.; Shotts (at Leith), 62s.; and Carron (at Grangemouth), 63s.

Sulphate of Ammonia.—The demand for sulphate of ammonia has again become stronger, and the price has advanced. The current quotation is now 13*l.* 12s. 6d. per ton for prompt lots, Glasgow or Leith, which is 5s. up from last week, and 15s. above the lowest point touched this year.

Scotch Steel Trade.—As is usual, the approach of the annual Fair Holidays has made the Scotch steel-makers rather busier, and there is some pressure to get orders hurried out before the works close on Friday at noon. Specifications for ship-plates have been plentiful during the past week, and the demand for boiler-plates has also been very good, but, on the other hand, no improvement has been shown in the demand for angles. Fresh business continues scarce, but contracts on hand are sufficient to keep the various establishments employed for some time. Light steel and sectional material are in fairly good request, and makers are being kept fairly busy this week. The majority of the steel works will resume after the holidays, on Monday morning, the 24th inst.

Malleable-Iron Trade.—In the malleable-iron trade business has been more active this week, but the tone of the trade has not improved. New orders are not very numerous, despite the fact that bars are still being offered on the basis of 6*l.* per ton, less 5 per cent. The holidays will be practically the same as those in the steel trade.

Scotch Pig-Iron Trade.—The local demand for the ordinary qualities of Scotch pig iron has lately been very moderate, and that from the South has not quite come up to expectations. There is a little more doing in export orders, but in this connection also there is room for improvement. Deliveries generally are more satisfactory this week on account of the approaching holidays. The demand for Scotch hematite is still very poor, and the price is nominally 65s. per ton.

INDIAN WATER-WORKS.—The proposals of the municipality of Cawnpore for the extension of the city waterworks have been approved by the Government of the United Provinces. The scheme includes a large multiple filtration plant for dealing with the water of the Ganges. The filters will have a capacity of 7,000,000 gallons per 24 hours. The consulting engineers are Messrs. H. Chabal, E.C.P, of Paris, and Walter Clemence, M.I. Mech. E., London.

NOTES FROM SOUTH YORKSHIRE.

SHEFFIELD, Wednesday.

Engineering Competition.—Although having more work in progress than at the same time last year, it was stated at the recent annual meeting of Messrs. Davy Brothers, Limited, engineers, Sheffield, that the financial result was short of expectations. Stress was laid upon the fact that in engineering, as in other big branches of trade, modern conditions are very much against big profits. The company was busily engaged last year, but the return for the work done was upon a much lower level of value. Amongst the factors pointed to as explaining this condition of affairs were low selling prices, increased cost of raw materials, keen foreign competition, and difficulties in foreign markets. However, the managing director of the company went so far as to give a hopeful expression of opinion upon the future.

South Yorkshire Coal Trade.—The labour unrest in the shipping world, which, of course, particularly affects the coal market, has had a considerable influence upon the position of affairs, which the coal trade still feels. The congestions at sidings and the accumulations of stock at collieries have both upset normal working. Manufacturing inquiries have been good, and are likely to be better when all the works have completed stocktaking. There has not been much underselling, prices remaining very steady. The majority of gas-coal consumers have fixed up their contracts and some are already taking additional supplies. The demand for slacks is quite as large as the collieries can cope with, and some qualities are higher priced. Stronger quotations are also made for coking smalls. The house-coal market remains quiet, and there is little buying, even of lots favourably offered. Most collieries are working half-time, and have considerable stocks on hand. Prices are firm and a good number of contracts have been arranged at current figures. Recent Change quotations are: Best branch hand-picked, 13s. to 14s.; Barnsley best Silkstone, 11s. to 12s.; Silkstone, 9s. to 10s.; Derbyshire house, 8s. to 9s.; large nuts, 7s. 3d. to 9s.; small nuts, 5s. 6d. to 6s. 6d.; Derbyshire brights, 10s. to 11s.; Yorkshire hards, 8s. 3d. to 9s. 6d.; Derbyshire, 8s. to 9s.; washed nuts, 7s. 9d. to 8s. 9d.; rough slacks, 5s. 3d. to 7s.; seconds, 4s. to 5s.; smalls, 1s. 6d. to 2s. 6d.

Iron and Steel.—The quietness in the iron market, usual at the period of the half-yearly stocktakings, has extended over into the present week. It remains to be seen what sort of effect the quarterly meeting at Birmingham will have upon the situation. Prices of hematites have been easier, particularly East Coast, and it is stated that in some instances buyers have obtained substantial advantages. The West Coast qualities remain about the same. The market for common irons shows little change, but competition has brought about a weakening of prices. Some undercutting by Derbyshire makers has placed Lincolnshire producers at a disadvantage. Competition continues to run high also in the billet trade. The home makers can, of course, do nothing to avert the influx of cheap Continental material, and consumers, in these days of cut profits, naturally favour the cheaper article. Bar iron makers remain fairly employed, with a somewhat better outlook. The position, however, does not warrant any alteration in the standing quotations. Steel-makers are favoured by the low price of tungsten, although this material has been a little firmer on the week. There is a good deal of uneasiness in the local steel trades upon the possible effects of the Government's insurance proposals. The present aspect of the steel trades is good, if business is not evenly distributed. The heavy branches show the most pronounced activity, and big quantities of armour-plate and gun-forgings are being turned out by the three East End houses. In some directions inquiries are hardly satisfactory, but the great majority of the makers have well-filled order-books, particularly the manufacturers of special steels. The foreign demand for this class of work has extended so much in recent years that what might almost be termed the monopoly of a few local firms has disappeared. First one manufacturer and then another has turned his attention to this branch until competition is now very keen, and profits are not so easily obtained as heretofore. In twist-drills and various kinds of mining tools and special steels, engineers' and shipbuilders' tools, and all kinds of high-speed steels, the inquiry continues to grow. Complaints are met with that the prices of many finished articles are not commensurate with the increased cost of raw materials.

WATERPROOFING CEMENT.—Messrs. Kerner, Greenwood, and Co., timber and builders' merchants, King's Lynn, have, we understand, now acquired sole control of the well-known waterproofing powder "Solita." They have registered it under the name of "Pudlo," considering it a better name, and in future it will be known by this name. They have prepared for distribution a little booklet on the subject, and will also answer any inquiry regarding the material. "Pudlo" is a white powder, which, when mixed with cement, makes it waterproof. The method of mixing and applying is as follows:—The cement is spread upon the floor, out of the wind, and the "Pudlo" is sprinkled over it through a fine sieve, is then shovelled well into the cement, the process being repeated until about 5 lb. in weight of "Pudlo" is mixed with about 100 lb. in weight of cement. Sand and water are then added to the cement in the usual way, the result being that the mixture is made absolutely waterproof. Messrs. Kerner, Greenwood and Co. have been selling this product for some considerable time, and have, they say, thoroughly tested the material. The British Government have, we understand, tried it for keeping heads of water back in fortifications.

NOTES FROM CLEVELAND AND THE NORTHERN COUNTIES.

MIDDLESBROUGH, Wednesday.

The Cleveland Iron Trade.—The pig-iron market is steady, and, on the whole, the situation is satisfactory for this time of year, which is usually a quiet season. Prospects are regarded as fairly bright, and most traders predict that the autumn will be characterised by considerable briskness. There are certainly grounds for taking a hopeful view of the future. Favourable reports continue to come to hand from the United States, and they should have some beneficial influence on the market. The most gratifying feature of the position, however, is the fact that the output of pig iron is well taken up, and as the season advances the make should be considerably more than fully absorbed, so that if production is not increased substantial reductions in stocks may be announced shortly. No. 3 g.m.b. Cleveland pig is steady at 47s. f.o.b.; whilst No. 1 is 50s. 3d.; No. 4 foundry and No. 4 forge each 46s. 6d.; and mottled and white iron each 46s. 3d.—all for early delivery. A rather better feeling in East-Coast hematite pig is reported. There are one or two inquiries in the market, but so far as can be ascertained, they do not appear to have, as yet, resulted in business. Mixed numbers can still be obtained from both makers and merchants at 61s. 6d., and that is the general market quotation. Business in foreign ore is at a standstill. Rubio, of 50 per cent. quality, is quoted 19s. to 20s. ex-ship Tees, and other descriptions of foreign ore are in the usual proportion. There is a fairly heavy demand for coke for local use, and requirements are met by a very full supply. Average blast-furnace qualities stand at 14s. 6d. delivered here.

Blastfurnacemen's Wages.—The average net selling price of No. 3 Cleveland pig iron for the three months ending June 30 last has been certified at 49s. 0.16d. per ton, as compared with 49s. 6 86d. for the first quarter of the year. There was, therefore, a reduction in price of 6.70d. per ton in the second quarter of the year. This means a reduction in blastfurnacemen's wages in the North of England of 0.50 (half of one) per cent., and brings wages from 21.75 per cent. above the standard to 21.25 per cent. above the standard.

Cleveland Miners' Wages.—At the quarterly meeting of the Cleveland Ironstone mine-owners and the miners' representatives, held at Middlesbrough this week, the owners stated that they regarded 26¼ per cent. as the standard of the wages that should be paid during the ensuing three months, against 27½ per cent., which had prevailed during the past quarter. A further meeting will be held on the 24th inst.

Trade Statistics.—The quarterly returns of the Middlesbrough Chamber of Commerce show that at the end of June of 79 furnaces built within the port of Middlesbrough 54 were in operation. The estimated output for the second quarter of the year is given at 580,000 tons, of which 380,000 tons was Cleveland pig iron, and 200,000 tons hematite, spiegel, basic, and other special irons. For the previous three months the total make was given at 600,000 tons, and for the second quarter of last year at 570,000 tons. The imports of foreign iron ore into Middlesbrough last quarter totalled only 436,926 tons, as compared with 549,742 tons for the previous three months, and 558,748 tons for the second quarter of 1910. The total value of goods other than coal and coke exported to foreign and colonial destinations from Middlesbrough during last quarter amounted to 2,122,575*l.*, and for the half-year to 4,225,793*l.*, being an increase for the quarter as compared with the corresponding time last year of 474*l.*, and an increase for the half-year as compared with the first half of last year of 295,120*l.*

Manufactured Iron and Steel.—There is not much new to report concerning the various branches of the manufactured iron and steel industries. New orders come slowly to hand, but producers of most descriptions have good contracts made, and values all round are well maintained. Common iron bars are 7*l.*; best bars, 7*l.* 7s. 6d.; best best bars, 7*l.* 15s.; packing iron, 5*l.* 15s.; iron ship-plates, 6*l.* 12s. 6d.; iron ship-angles, 7*l.*; iron ship-rivets, 7*l.* 5s.; iron girder-plates, 6*l.* 17s. 6d.; iron boiler-plates, 7*l.* 7s. 6d.; steel bars, 6*l.* 5s.; steel ship-plates, 6*l.* 15s.; steel ship-angles, 6*l.* 7s. 6d.; steel boiler-plates, 7*l.* 10s.; steel strip, 6*l.* 10s.; steel hoops, 6*l.* 12s. 6d.; and steel joists, 6*l.* 7s. 6d.—all less the customary 2½ per cent. discount. Cast-iron railway chairs are 3*l.* 12s. 6d.; cast-iron columns, 6*l.* 10s.; light iron rails, 6*l.* 10s.; heavy steel rails, 5*l.* 12s. 6d.; and steel railway sleepers, 6*l.* 10s.—all net cash at works. Iron and steel galvanised corrugated sheets, 24-gauge, in bundles, are 10*l.* 12s. 6d. to 10*l.* 15s. f.o.b.—less the usual 4 per cent.

CONTRACTS.—We understand that the Midland Railway-Carriage and Wagon Company, Limited, have accepted the tender of Messrs. Belliss and Morcom, Limited, for the equipment of the central power generating-station at their new works at Washwood Heath, Birmingham, to the specifications of Messrs. D. and A. Home-Morton, MM. Inst. C.E., MM.I. Mech. E., consulting engineers, Glasgow and Birmingham.—The Mirrlees Watson Company, Limited, Glasgow, have recently booked a large number of orders for surface-condensing plants and jet-condensing plants, complete, also for accessory machinery for same, both for this country and abroad, several items being repeat orders.—Messrs. Fraser and Chalmers, Limited, inform us that they have this week booked an important order for two turbines and blowers for the Stanton Iron-Works Company, Stanton, near Nottingham, to work in conjunction with existing reciprocating engines in connection with their extensive blast-furnaces.

NOTES FROM THE SOUTH-WEST.

Cardiff.—The steam-coal trade has ruled quiet. Colliery owners have shown no disposition to reduce prices for the best or second Admiralty coal for shipment before the August holidays; for other descriptions, however, slight concessions have occasionally been made for prompt loading. The best large steam coal has made 18s. 6d. to 19s. per ton; secondary descriptions have ranged from 16s. to 17s. 9d.; best bunker smalls from 10s. to 10s. 6d., and cargo smalls from 8s. 3d. to 8s. 9d. per ton. House coal has shown scarcely any change; the best ordinary descriptions have been quoted at 14s. 6d. to 16s. 6d. per ton, No. 3 Rhondda large at 17s. to 17s. 6d., and smalls at 10s. 6d. to 10s. 9d. per ton. No. 2 Rhondda large has brought 11s. 9d. to 12s. 3d., and smalls 8s. to 8s. 3d. per ton. Foundry coke has been quoted at 18s. to 20s. 6d. per ton, and furnace ditto at 16s. to 17s. per ton. As regards iron ore, Rubio has been making 18s. 6d. to 19s. 6d. per ton, upon a basis of 50 per cent. of iron, and charges, including freight, insurance, &c., to Cardiff or Newport.

Dowlais.—The Dowlais works have been well employed. The Goat Mill has been engaged on heavy sections of steel rails and tin-bar, and the Big Mill has been turning out fish-plates to accompany the heavy rails run off at the Goat Mill, as well as light railway *matériel* for pit-top use, curves, angles, &c.

South Wales Coal.—The shipments of coal—foreign and coastwise—from the six principal South Welsh ports—Cardiff, Newport, Swansea, Port Talbot, Neath, and Llanelly—in the first half of this year were as follows:—Cardiff—foreign, 7,992,922 tons; coastwise, 1,309,322 tons; total, 9,302,244 tons. Newport—foreign, 2,286,486 tons; coastwise, 355,764 tons; total, 2,642,250 tons. Swansea—foreign, 1,405,391 tons; coastwise, 136,383 tons; total, 1,541,774 tons. Port Talbot—foreign, 800,325 tons; coastwise, 70,061 tons; total, 870,386 tons. Neath—foreign (estimated), 80,000 tons; coastwise (estimated), 90,000 tons; total, 170,000 tons. Llanelly—foreign, 79,806 tons; coastwise, 24,958 tons; total, 104,764 tons. The aggregate shipments for the six months were, accordingly, 14,631,418 tons.

South Wales Mining Students.—A party of about thirty South Wales mining students left Cardiff on Saturday for the coal and iron mines of Silesia. The arrangements for this, the eighth tour of a Continental coal-field, were made through the officials of the Glamorgan County Council, assisted by Herr Williger, a Silesian engineer.

SIXTH CONGRESS OF THE INTERNATIONAL ASSOCIATION FOR TESTING MATERIALS, NEW YORK AND WASHINGTON, U.S.A.—The sixth Congress of the above Association will be held at New York and Washington in the beginning of September, 1912, under the auspices of the American Society for Testing Materials. Professor H. M. Howe, President of the Association, will act as President of the Congress, and Professor E. Marburg, of Philadelphia, as Secretary. The Congress will be divided into the Sections A, Metals; B, Concrete, Cement, Stone; C, Miscellaneous. The manuscripts of papers to be presented at the Congress must be sent in to the head office of the Association, Nordbahnstrasse 50, Vienna II., not later than January 1, 1912. Members desirous of taking part in the Congress are requested to notify their intention as soon as possible to the representative of the Association for Great Britain, Mr. G. C. Lloyd, Secretary of the Iron and Steel Institute, 28, Victoria-street, London, S.W.

EIGHTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY, WASHINGTON AND NEW YORK, U.S.A.—The Eighth International Congress of Applied Chemistry will be held in Washington and New York, U.S.A., from September 4 to 13, 1912, under the patronage of the President of the United States. The Hon. President of the Congress is Professor Edward W. Morley, Sc.D., Ph.D., LL.D.; the President is Mr. William H. Nichols, Sc.D., LL.D., and the secretary Dr. Bernhard C. Hesse, 25, Broad-street, New York City. The Congress is divided into twenty-four sections and sub-sections. Papers will be accepted for reading and discussion in all the sections, preference being given to those specially adapted for international discussion. They must be sent in not later than July 1, 1912. A preliminary pamphlet has been issued, and may be obtained from the hon. secretary of the British Organising Committee, Mr. Charles G. Cresswell, Society of Chemical Industry, Palace Chambers, Westminster, S.W.

ADMIRAL TOGO'S VISIT TO MESSRS. VICKERS' WORKS.—Admiral Togo, accompanied by his suite and the naval and some other members of the Japanese Embassy, left London on Saturday, the 8th inst., for Barrow-in-Furness, to visit the naval construction works of Messrs. Vickers, Limited. Mr. Albert Vickers, the chairman, and Sir Trevor Dawson, managing director of the company, also accompanied him. The works at Barrow have special attractions for Admiral Togo. It was there that the Vickers Company designed and built his flagship during the late war, the Mikasa, while later the Katori was completed for the navy of the Mikado. At present there is in course of construction at Vickers' works an armoured cruiser which is expected to surpass in all fighting qualities any warship yet laid down. This vessel, with which considerable progress has been made, has been designed by Mr. T. G. Owens, the naval constructor and director of the company. On Monday Admiral Togo inspected the vessel and her turbine and ordnance machinery, and was also present at gun trials at the company's range at Eskmeals, on the Cumberland coast.

THE PHYSICAL SOCIETY OF LONDON.

AT the meeting of the Physical Society of London, held on June 9, 1911, at the Imperial College of Science, Professor H. L. Callendar, F.R.S., in the chair, a paper on "*The Lüders Lines on Mild Steel*" was read by Mr. W. Mason.

Previous investigations have shown that Lüders' lines on specimens of mild steel and wrought iron, strained in tension, are inclined at about 50 deg. to the axis of pull. For tests in compression the information available is not precise, and though the angle of the lines with the direction of the compression is commonly understood to be about 40 deg., some doubt has been thrown on this point.

The author had found previously that the lines are well developed on the surface of mild-steel tubes. Since it was easy to obtain a compressive stress of practically uniform distribution in tubes under end pressure, while at the same time a hoop tensile stress could be induced by internal fluid pressure, the author confined his attention to the lines on tubular specimens. These were of mild steel, either hot or cold drawn, and most of them were annealed. They varied in bore from 2½ in. to 3 in., and in thickness of wall from about 0.08 in. to 0.125 in. Four sets of tubes were tested under end-loading, simultaneously (for the most part) with internal water-pressure, these loadings being so arranged as to give at the yield-point ratios of the longitudinal compressive stress to hoop tensile stress ranging from 0.25 to ∞.

The Luders lines on the outer surface appeared at the yield-point indicated by the extensometer—*i.e.*, their appearance coincided with the commencement of the large "yield" strain. In all cases where there were lines on the inner and outer surfaces of a tube, an inner and outer line, and also the ends of these lines, were found to be radially opposite, showing that the lines were traces of surfaces or canals of disturbance which passed through the tube-wall, and indicating, moreover, that the disturbance spread spirally onwards, and not outwardly from a line initially formed on the more severely stressed inner surface.

The inclination α of the lines to the axis of the tube was found to vary in the following way for tubes under end load and internal pressure:—

$$\text{For } \frac{\text{longitudinal stress}}{\text{hoop stress}} = 0.25,\ \alpha = 42 \text{ deg. (about)}.$$
$$\text{,, ,, ,, } = 1,\ \alpha = 45 \text{ deg. (about)}.$$
$$\text{,, longitudinal ,, stress only, } \alpha = 50 \text{ deg. (about)}.$$

For values between 0.25 and 1, and between 1 and ∞, α became progressively larger.

Some tests of tubes under external water pressure and longitudinal tension gave results similar to those above mentioned. The directions of the lines with respect to the axes of like stress were practically the same, though the inclinations to the axes of the tubes were now complementary to the values of α quoted above.

The conclusion is drawn that the Lüders surfaces have the same or approximately the same inclination to an axis of simple pull or simple push. With stresses of opposite sign at right angles to each other the lines and surfaces are more inclined to the stress of greater intensity, and with equal intensities the surfaces are at about 45 deg. The author suggests that if a shear stress of given intensity be the only condition for that spreading of plastic strain which commences at the yield-point, then there is no reason why there should be any variation in the angle of the Lüders lines and surfaces. The variation suggests that not only the maximum shear stress—*i.e.*, the half difference of the greatest and least principal stresses—but also the magnitudes of the principal stresses, are factors in producing the yielding condition in mild steel.

Dr. Chree said Lüders' lines seemed to possess a double interest. If their first existence coincided in time with the ending of linearity in the stress-strain relation, their presence intimated that the ordinary mathematical equations had ceased to apply. In this connection their utility would be greater if the stress function supposed to determine the elastic limit were greatest at a point or small area visible to the eye, instead of, as in the present case, over the whole inner surface of a cylinder. The phenomenon seemed, however, also interesting in itself. The nature of the change in the material and the mode of propagation of the altered volume would be more easily studied if the altered material could be recognised in sections of the cylinders.

Professor Coker asked whether the lines were a surface phenomenon produced by the stresses in the oxide.

Professor C. A. M. Smith pointed out that slipping in the material takes place in a definite manner, even after quite a long time, and that the lines might be due to this.

Mr. E. H. Rayner pointed out that the elastic constants in the two directions would probably be different, and that the compression might put on shear, resulting in lines only appearing in one direction.

Dr. A. Russell asked the author if his results threw any light upon the phenomena obtained when wires are drawn.

Mr. Maclachlan asked the author if he had ever tried polishing the surface of his tubes. His own experiments made on the compression of solids showed that the lines were not always spirals, but approximated to a section of the cylinder made by a plane inclined at 45 deg.

The author, in reply, stated that he did not know whether the lines occurred at the elastic limit, or just after. The lines were not a surface phenomenon, as they were obviously related to the bend in the stress-strain diagram. Mr. Rayner's difficulty was got over by reversing the stresses. The lines were not due to massive slipping, but to the propagation of a disturbance.

A paper on "*A New Method of Harmonic Analysis by Averaging Selected Ordinates*" was read by Professor S. P. Thompson.

Assume with Fourier that the curve representing any periodic single-valued function of x may be expressed by the harmonic series

$$y = A_1 \sin x + A_2 \sin 2x + A_3 \sin 3x + \ldots + B_1 \cos x + B_2 \cos 2x + B_3 \cos 3x.$$

Then to find the coefficient of any term, A_n or B_n, it suffices—subject to a limitation stated below—to measure off on the curve $2n$ equidistant ordinates over one period; that is, spaced at successive intervals apart of π/n. Then, having reversed the sign of every alternate ordinate, the simple algebraic mean of them gives the coefficient sought. For cosine-coefficients the first ordinate must be taken at the origin; while for sine-coefficients the first ordinate must be taken at a point $\frac{1}{2}\frac{\pi}{n}$ from the origin. In symbols this is—

$$A_n = \frac{1}{2n}\left\{ \begin{array}{c} y_{\frac{1}{2}\pi/n} - y_{\frac{3}{2}\pi/n} + y_{\frac{5}{2}\pi/n} - y_{\frac{7}{2}\pi/n} + \ldots \\ - y_{\frac{4n-1}{2}\pi/n} \end{array} \right\};$$

$$B_n = \frac{1}{2n}\left\{ \begin{array}{c} y_0 - y_{\pi/n} + y_{2\pi/n} - y_{3\pi/n} + \ldots \\ - y_{(2n-1)\pi/n} \end{array} \right\}.$$

The limitation is that if, in finding the nth harmonic, there be present also the 3nth, or the 5nth, or the 7nth, &c., these will be included in the average found by the process, and must, if present, be separately determined and eliminated.

The process is much facilitated by the use of templates of transparent celluloid having equispaced vertical lines engraved upon them. They are laid down on the curve, and the values of the selected ordinates are thus readily measured off. For analysis of valve motions, of alternating-current curves, of tidal observations, and diurnal magnetic variations, the method presents certain advantages, as it requires no multiplication of ordinates by sines or cosines.

The President commented upon the extreme ease with which the method adapted itself to the analysis of experimental curves.

Dr. Russell remarked that the method can be usefully employed in interpolation as well as in harmonic analysis. In this connection he gave a brief *résumé* of Gauss's extension of Lagrange's interpolation formula. He also pointed out certain cases in which Fourier's analysis fails to be of practical use.

Sir G. H. Darwin communicated the following remarks:—In 1874 Mr. Archibald Smith published, in the Admiralty Scientific Manual on "Deviations of the Compass," schedules whereby the multiplications in the usually accepted process are simple. This same arrangement has been in use for the harmonic analysis of tides since 1870; and in his "Manual of Tidal Observations," Major Baird gave multiplication tables for the sines of 15, 45, 60, 75 deg., which render this part of the work so easy that avoidance of all multiplication hardly seems necessary. In 1884, in "Tables and Formulæ to Facilitate the Computation of Harmonic Coefficients," General Sir Richard Strachey gave rules which reduce the multiplications still further. In both these schemes Professor Thompson's principle is used for some of the higher harmonics. Smith's and Strachey's schedules are arranged for 24 hourly values, but they may be equally well used for 12 ordinates. Schedules for the use of any other number of ordinates would have to be prepared specially, and in such cases Professor Thompson's rules might prove very convenient.

A "*Demonstration of the Subjective Nature of the Difference Tone*" was given by Professor S. P. Thompson.

Two tuning-forks of frequencies 3328 and 3584 were sounded loudly. On striking the second the difference tone was heard, but while the notes from the two forks seemed to come in a definite direction from an external source, the difference tone seemed to be located in the ear itself.

A demonstration of "*Spinning-Tops and Gyroscopic Apparatus*" was given by Sir George Greenhill.

A 52-in. Otto bicycle-wheel was shown mounted on an axle with ball bearings, and spun by hand with the point in a small cup, to serve as a spinning-top visible to a large audience.

The gyroscopic apparatus is made of an ordinary 28-in. bicycle-wheel, the axle screwed into a stalk of a short length of rifle barrel, suspended from a lug on a bicycle hub; the hub is fastened to an iron bracket, which is bolted to the underside of a beam or sleeper, large enough to absorb vibration, and resting on two step-ladders. The wheel is spun by hand, and the axle is projected to obtain any desired gyroscopic motion, undulating, looped, or with cusps.

The wheel can be detached by unscrewing the pin through the lug, and can then be used like the large wheel as a spinning-top, or as the "Top on the top of a Top" described in "Maxwell's Life."

If the wheel be put out of balance by a bar through the spoke and the axle be held, it will serve as a pendulum, making oscillations however large, or complete revolutions; and the effect may be investigated of varying the angle of the axle with the vertical.

"*A Model Illustrating the Passage of a Light Wave Through Quartz*," constructed by Professor H. N. Allen, of Poona, was described by Dr. H. S. Allen.

If a crystal is so cut, and a wave sent through it in such a way as to avoid separation of the two component waves by double refraction, it is easy to construct models showing how a vibration gradually alters in form as it passes through the crystal. The model exhibited illustrates the passage of a wave originally plane polarised through a crystal which rotates the plane of polarisation of light sent along its axis (quartz). The direction of propagation is oblique to the axis of the crystal. It is assumed that the crystal has been cut so that the surface of incidence is perpendicular to the direction of propagation of the wave. As the wave progresses the linear vibration opens out into a counter-clockwise elliptical one, while the major axis of this ellipse rotates in the counter-clockwise direction. The minimum ratio between the axes is reached when the retardation is half-a-period. A retardation of a whole period gives a linear vibration again, and so on. If the model is cut by a series of parallel planes the sections give the form of the elliptic vibration as the wave travels through the crystal. The instantaneous wave forms can be drawn on the surface of the model.

A paper on "*The Measurement of Contact Differences of Potential*," by Professor A. Anderson and Mr. J. E. Bowen, was taken as read.

The paper describes two methods of measuring the contact differences of potential of pairs of metals. The first, or deflection, method depends on the property which a radioactive source has of destroying a field of electrostatic force in air, and the second, or null, method on the possibility of determining by means of such a source whether such a field exists between two plates at zero potential. Measurements were made on 10 different metals, and it was found that both methods gave practically the same results provided that the time which was allowed to elapse between the two measurements was sufficiently small. The addition law was verified.

A paper entitled "*A Short Table of Circular and Hyperbolic Functions for Complex Values of the Argument*," by Mr. A. Johnstone, was also taken as read.

FOREIGN ENGINEERING PROJECTS.

WE give below a list of colonial and foreign engineering projects, for several of which tenders are asked. Further data concerning them can be obtained from the Commercial Intelligence Branch, Board of Trade, 73, Basinghall-street, E.C.

Canada: H.M. Trade Commissioner for Canada reports that estimates are being prepared for water-works extensions at a town in Ontario, at a probable cost of 1,000,000 dols. (about 205,000*l.*). The Imperial trade correspondent at Toronto (Mr. F. W. Field) reports that a company, with a capital of 10,000,000 dols. (about 2,055,000*l.*), has been granted a charter to manufacture all kinds of sales books, cheque books, wooden wares, paper wares, registers, &c. A company has been formed with a capital of 3,500,000 dols. (about 718,000*l.*) for the purpose of manufacturing railway locomotives and rolling-stock and also all kinds of steam, gasoline, oil, and other engines. A company has been incorporated, with a capital of 2,000,000 dols. (about 411,000*l.*), for producing and refining petroleum and its products, and for mining metals, ores, and minerals. It is also granted the right to manufacture soap, candles, perfumery, and toilet articles. With reference to the notice on page 44 ante, relative to a call for tenders for the construction of a breakwater, and of wharves, the dredging of a channel and basin, and the construction of a dry dock and ship-repairing plant of the first class at St. John Harbour East (Courtenay Bay), H.M. Trade Commissioner for Canada has forwarded a copy of the specifications, form of tender, &c., which may be seen by British firms at the Commercial Intelligence Branch of the Board of Trade, 73, Basinghall street, London, E.C. Tenders will be received by the Secretary, Department of Public Works, Ottawa, up to 4 p.m. on August 10.

Spain: The *Gaceta de Madrid* of June 24 notifies that the "Sociedad Anónima Tranvía de Orihuela à Crevillente" has applied to the General Directorate of Public Works for a concession for the construction and working of a steam tramway from Orihuela to Crevillente. It is proposed that two years be allowed for the completion of the line. The initial rolling-stock will comprise four locomotives, four first class and ten second-class coaches, four covered and eight uncovered wagons.

Sweden: The British Vice-Consul at Nyköping (Mr. A. Helander) reports that tenders are invited by the Swedish State Railways Administration for the construction of a new line between Enstaberga (outside Nyköping) and Aby (outside Norrköping). Tenders should be marked "Anbud a anläggande af järnväg mellan Enstaberga och Aby, Registratorns Byra," Stockholm, where they will be received up to noon on August 15. The new line, which is to be opened for traffic not later than September 1, 1915, will pass through mountains, and considerable blasting operations will be necessary. Copies of the drawings, specifications, &c. (in Swedish) can be obtained by British firms through the British Vice-Consulate, Nyköping, on payment of the sum of 3*l.*, the greater part of which will be returned upon receipt of a *bonâ-fide* tender.

Italy: Referring to the notice on page 739 of our last volume relative to the construction of a breakwater and kindred works in Catania Harbour, the *Gazzetta Ufficiale* (Rome) of June 26 notifies that, as no award has been made in respect of this contract, tenders are again invited, and will be opened on July 24 simultaneously at the Ministero dei Lavori Pubblici, Rome, and at the Prefettura di Catania, Catania. The upset price is put at 2,450,000 lire (98,000*l.*), and a deposit of 120,000 lire (4800*l.*) will be required to qualify any tender. Although this contract will doubtless be awarded to an Italian firm, nevertheless the carrying out of the work may involve the purchase of some materials out of Italy.

ROAD LOCOMOTIVES.—The value of the road locomotives exported from the United Kingdom in April was 42,496*l.*, as compared with 40,157*l.* in April, 1910, and 29,968*l.* in April, 1909.

"ENGINEERING" ILLUSTRATED PATENT RECORD.

SELECTED ABSTRACTS OF RECENT PUBLISHED SPECIFICATIONS UNDER THE ACT OF 1907.

The number of views given in the Specification Drawings is stated in each case; where none is mentioned, the Specification is not illustrated.

Where inventions are communicated from abroad, the Names, &c., of the Communicators are given in italics.

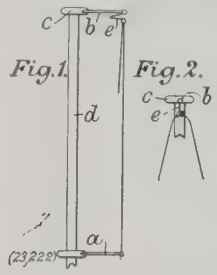
Copies of Specifications may be obtained at the Patent Office, Sale Branch, 25, Southampton Buildings, Chancery-lane, W.C., at the uniform price of 8d.

The date of the advertisement of the acceptance of a Complete Specification is, in each case, given after the abstract, unless the Patent has been sealed, when the date of sealing is given.

Any person may, at any time within two months from the date of the advertisement of the acceptance of a Complete Specification, give notice at the Patent Office of opposition to the grant of a Patent on any of the grounds mentioned in the Act.

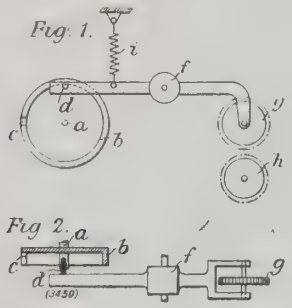
ELECTRICAL APPARATUS.

23,222/10. G. Ludecke and the Imperial Lamp Works (Brimsdown), Limited, Brimsdown. Electric Lamps. [5 *Figs.*] October 7, 1910.—The invention consists in providing, in connection with the rigid upper supporting arms for the filament, secondary supports of thin wire bent to an acute angle and each of the arms of which is equally inclined to the filament, the arrangement being such that contractions or



vibrations of the filament are compensated for by movement of the arms. The rigid lower supporting arms *a* and rigid upper supporting arms *b* are connected to the beads *c* of the central glass stem *d*. To the arms *b* the secondary supports *e* of thin wire are connected. In order to prevent too sharp bending of the filament, the secondary supports *e* are provided with a small spiral of two or more windings through which the filament is passed as shown in Fig. 2. (*Accepted May* 3, 1911.)

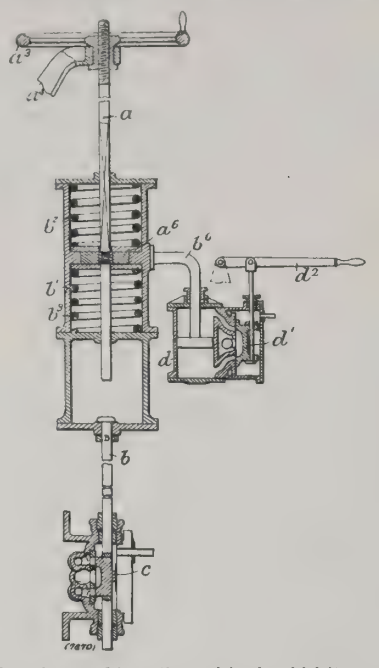
3450/11. Firm H. Aron Elektrizitatszahlerfabrik, G.m.b.H., Charlottenburg, Germany. Prepayment Electric Meters. [2 *Figs.*] April 6, 1910.—In a prepayment electric meter, according to this invention, a normally inoperative coupling between the prepayment mechanism and the meter switch is rendered operative only after a part of the meter has rotated through a determined angle or distance, through which period current can pass through the meter without prepayment, whereupon further current can be obtained only after prepayment by the insertion of a coin in the ordinary way. *a* is the axle of a counting-wheel of the meter. On this axle is mounted a disc *b* having a slot *c*. A pin *d* carried by a lever *f* bears against the inner edge of the disc *b*. A spring *i* has a constant tendency to pull the end of the lever *f* in an upward direction. The disc *b* is driven by the axle of the meter and turns round gradually until the slot *c* comes opposite or in front of the pin *d*. The spring *i* is now free to pull the lever *f* upwards, and thus causes



the pin *d* to pass up and through the slot *c*. By this means the other end of the lever *f*, which carries the toothed wheel *g*, is moved down into engagement with a toothed wheel *h*. The toothed wheel *g* is permanently connected to the axle *a* of the meter by mechanism (not shown). The toothed wheel *h* belongs to the prepayment mechanism of the meter. When the wheels *g* and *h* have been brought into engagement with each other, as above described, the meter works in the same manner as an ordinary prepayment meter; that is to say, it opens its switch automatically to cut off the current when the amount of electricity determined by the previously inserted coin has passed through. When the switch is opened and the current cut off, no further current can be taken by the consumer until after he shall have inserted another coin into the meter. The two toothed wheels *g* and *h* remain in engagement with each other, because the pin *d* is kept out of the disc *b* by the action of the spring *i*. (*Accepted May* 10, 1911.)

GUNS AND EXPLOSIVES.

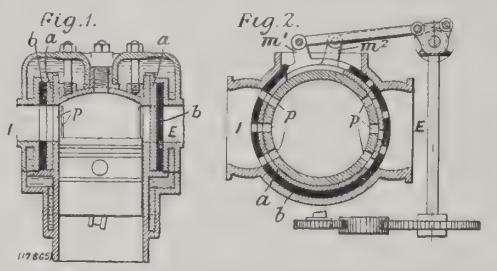
7870/10. R. H. S. Bacon and F. Duncan, Coventry. Ordnance-Training Gear. [2 *Figs.*] April 1, 1910.—In training control gear for ordnance, according to this invention, a supplementary hand-controlled valve is provided by means of which the turntable may be caused to rotate rapidly in either direction, as required, without disturbing the position at which the main controlling hand-wheel is set. The training control valve-spindle *a* has at one end a screw-thread, on which is mounted a nut forming the boss of a hand-wheel a^3 mounted in a bearing a^4. The spindle is arranged to move axially, but is prevented from rotating; rotation of the hand-wheel traverses the valve on its seat. The valve-spindle is in two portions, *a* and *b*; the end of one portion *a* is provided with a disc a^6, and the other *b* is attached to a cylinder b^1, in which the disc a^6 can move axially. Between the ends of the cylinder and the disc springs b^2, b^3 are inserted, either of which is strong enough to overcome the frictional resistance of the valve, and suitable centering stops are provided to determine the mid-position of the disc in the cylinder. It is, therefore, obvious that on rotating the hand-wheel a^3, the valve spindle *a*, *b*, cylinder b^1, disc a^6, and springs b^2, b^3 move as one piece. By means of a crosshead b^6 the cylinder b^1 is attached to the piston of a double hydraulic cylinder *d* controlled by a valve d^1 actuated by a lever d^2. The valve and ports are so arranged that when the valve is in its mid-position both ends of the cylinder are put to exhaust. When pressure is admitted to one or other end of the cylinder *d* by moving the lever d^2 the training



control-valve *c* is moved from the position in which it may be situated to one or other extreme end of its stroke, thereby causing the turntable to rotate at maximum speed either in the same or opposite direction to which it was rotating. On the supplementary lever d^2 being centred, the hydraulic cylinder is put to exhaust, and the compressed spring b^2 or b^3 extends and returns the training control-valve *c* to its original position. (*Accepted May* 10, 1911.)

GAS ENGINES, PRODUCERS, HOLDERS, &c.

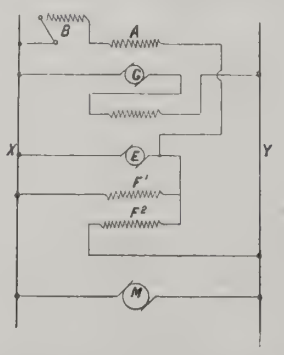
17,865/10. J. Hay, London. Internal-Combustion Engines. [5 *Figs.*] July 27, 1910.—In an internal-combustion engine, according to this invention, two cylindrical valves are placed outside the upper portion of the cylinder and have ports cut in them. The valves are oscillated and control ports in the cylinder wall. *a*, *b* are the two valves, the valve *a* being the inner one and sliding on the outside of the upper portion of the cylinder.



In the upper portion of the cylinder, ports *p* are cut and lead to the inlet-passage I and to the exhaust-passage E. Similar ports are cut in the valves *a*, *b*, the relative positions of these ports being determined by the required timing of the inlet and exhaust functions. The valves are operated from the crank-shaft through the medium of the half-speed shaft through arms m^1, m^2. (*Accepted May* 10, 1911.)

LIFTING AND HAULING APPLIANCES.

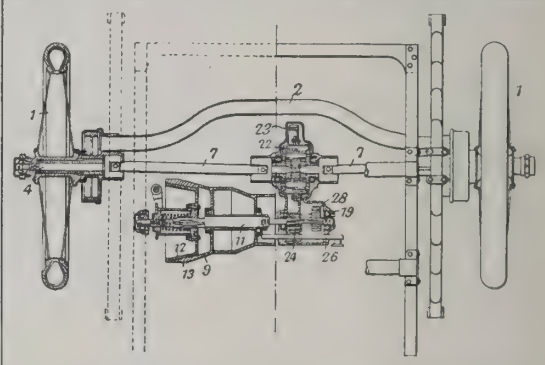
29,728/10. Crompton and Co., Limited, J. C. Macfarlane, and H. Burge, Chelmsford, and A. Williams, London. Electrically-Operated Driving Systems. [1 *Fig.*] December 21, 1910.—In electrically-operated hauling or winding machinery, or electrically-operated rolling-mills, wherein wide variations in torque and speed occur, while the demand for power from the supply is restricted, and in which current is supplied to the working motor from a direct-current generator provided with a variable field separate excitation so that it is



capable of delivering current at a variable voltage, there is employed on the working motor a field winding which is connected between the positive brush of the generator and the positive brush of the exciter. G represents a direct-current generator provided with a variable field excitation A and a hand-controlled resistance B, so that it is capable of delivering its current at any desired voltage. E is an exciter direct coupled to the generator, and developing exciting current at a constant voltage. X and Y are supply conductors connected to the brushes of the generator G, and leading current to the motor M. The field of the motor is provided with a winding F^1, excited directly from the brushes of the exciter E. A second winding F^2 is provided, and is connected from the positive brush of the exciter or from the positive pole of the supply to the conductor Y. (*Accepted May* 10, 1911.)

MOTOR ROAD VEHICLES.

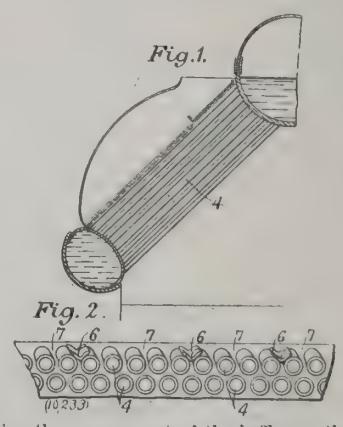
11,196/10. C. H. Dent, Tamworth, and Dent Motors, Limited, Birmingham. Transmission Gear. [4 *Figs.*] May 6, 1910.—This invention relates to motor road-vehicles in which the rotation of the engine is transmitted to the driving gear by means of a single belt and a pair of variable-speed cones, drums, or pulleys. The rear wheels 1 of the vehicle are rotatably supported at the outer ends of a curved transverse bridge-piece or rigid axle 2, and are driven from the outer members of a bevel differential gear, or from the sun-wheel of a planetary differential gear, by means of transmission shafts 7, which are connected by Cardan joints to the said members and to short axles 4 secured to the hubs of the rear wheels 1. The rear cone, which preferably consists of a pulley provided with three speed or belt surfaces and arranged with its largest diameter outwards, is located on one side of the centre line of the vehicle, while the differential and reversing gearing, and in the majority of cases the reducing gearing, is arranged on the other side of the said centre line and as near as possible to the latter. The rear cone is loosely mounted on its shaft 11, but is adapted to be connected to and freed therefrom by any suitable construction of clutch. The clutch preferably consists of a cone 12 which is mounted on a squared or castellated part of the shaft 11 and is constantly pressed by a spring into engagement with a coned surface 13 formed in the interior of the outer end of the rear cone.



The outer end of the shaft 11 is mounted in a bearing supported by one of the side members of the frame or chassis of the vehicle, while the inner end of the shaft is mounted in a bearing or bearings provided in a box or casing 19 which is supported from one or more of the transverse members of the frame or chassis of the vehicle. The rear of this box or casing is made of such size as to accommodate a cage 22 containing the differential gear and a large toothed wheel 23 secured to the exterior of the said cage, while its front end is made of such size and shape as to receive and support the mechanism by which the large toothed wheel 23, and therefore the cage, is rotated in either direction. This mechanism preferably consists of a pinion 24 slidably mounted on the inner end of the shaft 11, a fork embracing the pinion and secured to a spindle 26 slidably mounted in the box or casing 22, and a reversing shaft provided with a wheel 28 adapted to be engaged by the pinion 24 and with a pinion, not shown, always in mesh with the large wheel 23. When the cone 12 is in engagement with the cone surface 13 of the rear cone, the drive is transmitted at a reduced speed to the wheels 1, which will be rotated either in a forward or in a backward direction, the direction of rotation being determined by the position of the pinion 24; that is to say, whether the pinion 24 is in engagement with the large toothed wheel 23 or with the wheel 28. Further, when the cone 12 is disengaged from the rear cone, the latter will rotate without transmitting the drive to the wheels 1. (*Accepted May* 10, 1911.)

STEAM ENGINES, BOILERS, EVAPORATORS, &c.

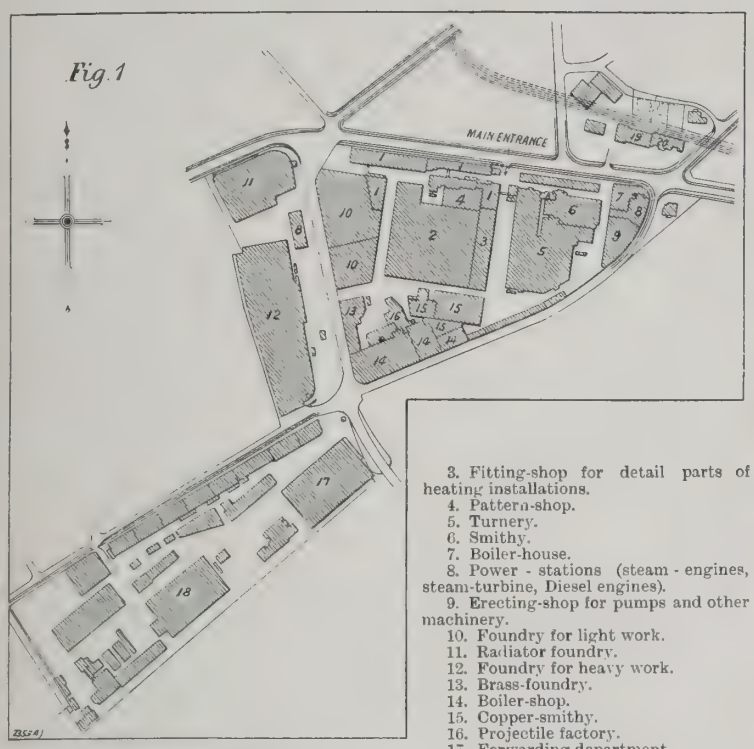
10,233/10. A. F. Yarrow, Blanefield. Water-Tube Boilers. [8 *Figs.*] April 26, 1910.—In water-tube boilers uniformity of distribution of the heated gases over the surfaces of the water-tubes is secured by adjusting, by means of baffles, preferably removable or displaceable, on the uptake side of the banks of water-tubes, the space for the passage of the furnace gases between the water-tubes, so as to present a substantially uniform resistance to the passage of these gases over all paths which they can take in passing from the combustion space to the uptake. This result may be attained in a number of ways, one of which is illustrated in the drawings, Fig. 1 being a part transverse section of a water-tube boiler of the Yarrow type, fitted with removable baffles, and Fig. 1*a* a perspective view on an enlarged



scale, showing the arrangement of the baffles on the outermost row of one bank of water-tubes. As therein shown, angle-bars 6 or other suitable rolled sections are placed between adjacent tubes of the outermost row of tubes 4, spaces being left between the tubes for the passage of the gases as shown at 7. The distribution of the angle-bars 6 is so varied as to present a greater obstruction to the flow of the gases along the shorter paths than along the longer paths, so as to equalise as much as possible the resistance to flow along all paths. Thus, towards the centre of the bank of tubes, the angle-bars may be placed so that between successive angle-bars there will be two or three vacant inter-spaces 7, while towards the ends of the boiler the angle-bars are spaced more widely, thereby leaving a greater cross-section of free space for the flow of the gases. (*Accepted May* 3, 1911.)

WORKS OF MESSRS. SULZER BROTHERS, WINTERTHUR, SWITZERLAND.

(*For Description, see Page* 83.)



1. Commercial and technical offices.
2. Erecting-shop for Diesel engines and for refrigerating plant.
3. Fitting-shop for detail parts of heating installations.
4. Pattern-shop.
5. Turnery.
6. Smithy.
7. Boiler-house.
8. Power - stations (steam - engines, steam-turbine, Diesel engines).
9. Erecting-shop for pumps and other machinery.
10. Foundry for light work.

THE WORKS OF MESSRS. SULZER BROTHERS, WINTERTHUR.

On Wednesday next, the 26th inst., a number of the members who are taking part in the meeting of the Institution of Mechanical Engineers at Zurich, will make an excursion to Winterthur to visit the works of Messrs. Sulzer Brothers. The history of this large Swiss engineering establishment is an interesting one; it is, briefly, as follows. The first member of the Sulzer family who turned his attention to industrial pursuits was Solomon Sulzer, who was born in January, 1757. Solomon Sulzer had studied theology and was on the point of accepting an appointment as pastor in a township in close proximity to Zurich, when he decided to abandon this position and to follow what was, after all, his real calling—the trade of a brass-founder. At that time, in the latter part of the eighteenth century, an intelligent craftsman had established a business at Schaffhausen; this craftsman had started the manufacture of brass castings, and had in the course of a very short period become a dangerous competitor to the coppersmiths of the district. Young Sulzer had heard many reports concerning this brass-founder and his successes. He called on him at his shop at Schaffhausen, purchased his secret for 500 florins, equal to about 50*l*., learned the trade, and came to Winterthur, where he established himself as a tradesman.

This appears now a most simple matter; young Sulzer, however, did not find it so. He not only experienced in the usual way that "all commencements are difficult" in themselves, but in his case he had to deal with local prejudice. In the mind of the inhabitants he was introducing a secret trade, and was looked upon with suspicion. He was only allowed to put down his plant—a very small one, as might be expected—close to the town ditch, and the fight was an uphill one. He first manufactured by casting a large number of small articles which until then had been made in the copper-smithy. He gradually increased his installation, and added to it a small turnery and a small fitting-shop. The business was commencing to prosper when the French Revolution broke out; this stopped all trade for many a year, and Solomon Sulzer left his son in charge of the plant and went to Lorraine in 1806, to earn a livelihood until better times supervened, but he died there in 1807. He was succeeded in the Winterthur business by his said son, Jacob Sulzer, who was followed by his two sons, the first brothers Sulzer, who in turn were followed by Messrs. H. Sulzer-Steiner, A. Sulzer-Grossmann, E. Sulzer-Ziegler, and J. Sulzer-Imhoof. The present owners of the works are the two last-named gentlemen, with Messrs. Carl Sulzer-Schmid, Albert, Robert, and Hans Sulzer, and Richard Ernst.

The first brass foundry, as it was taken over in 1807 by the son of the founder, occupied an area of only 54 sq. m. (590 sq. ft.), and one cast only, a very small one, was made per week. From these small beginnings has sprung up the huge establishment with which we have now to deal. We do not propose to detail the various developments undertaken by the succeeding generations of Sulzers—this would make too heavy demands on our space—nor do we propose to enter into the particulars of the part played in these developments by the late Mr. Charles Brown and other collaborators of the owners. We shall only state that whereas in the early days two foundrymen and two labourers formed the whole staff, the blowing-engine being driven by a mule on casting days, the staff now numbers 4000 men at Winterthur, of which 1400 are occupied in the foundries. The total staff, including the Ludwigshafen Works, amounts to 5500. The Ludwigshafen Works were put down in 1881. The works at Winterthur now cover an area of 70,000 sq. m. (83,700 sq. yards); those at Ludwigshafen an area of over 30,000 sq. m. (35,800 sq. yards).

The Winterthur Works are shown in the plan, Fig. 1, on Plate XIV., a reference to the various departments being annexed. We also illustrate these works in the view, Fig. 2, on the same plate, which also shows Messrs. Sulzer's Ludwigshafen establishment. Fig. 3, also on Plate XIV., shows an extension in course of completion at Ober-Winterthur, as stated further on.

When the Winterthur works were first put down on the site they now occupy—in the year 1834—the proprietors little expected that they would require such a marked extension. The extension has been gradual, but during the last ten years, more especially, the business to be coped with in the various departments throughout the works has increased to such a degree that Messrs. Sulzer have been repeatedly compelled in this later period to enlarge their plant. It so occurred that at the different epochs separating each periodical extension made with a view to meet the increase in demand, the plant became inadequate for a short time, and manufacture had to be decentralised until it could be centralised again on the completion of a new extension or transformation. In this way the owners built, in 1910, the new erecting-shop [illegible] Diesel engines, together with other shops, a[illegible] they are now occupied in reorganising their old [illegible]shops so as to still better adapt them to the va[illegible]us processes of manufacture of their different sp[illegible]ialities.

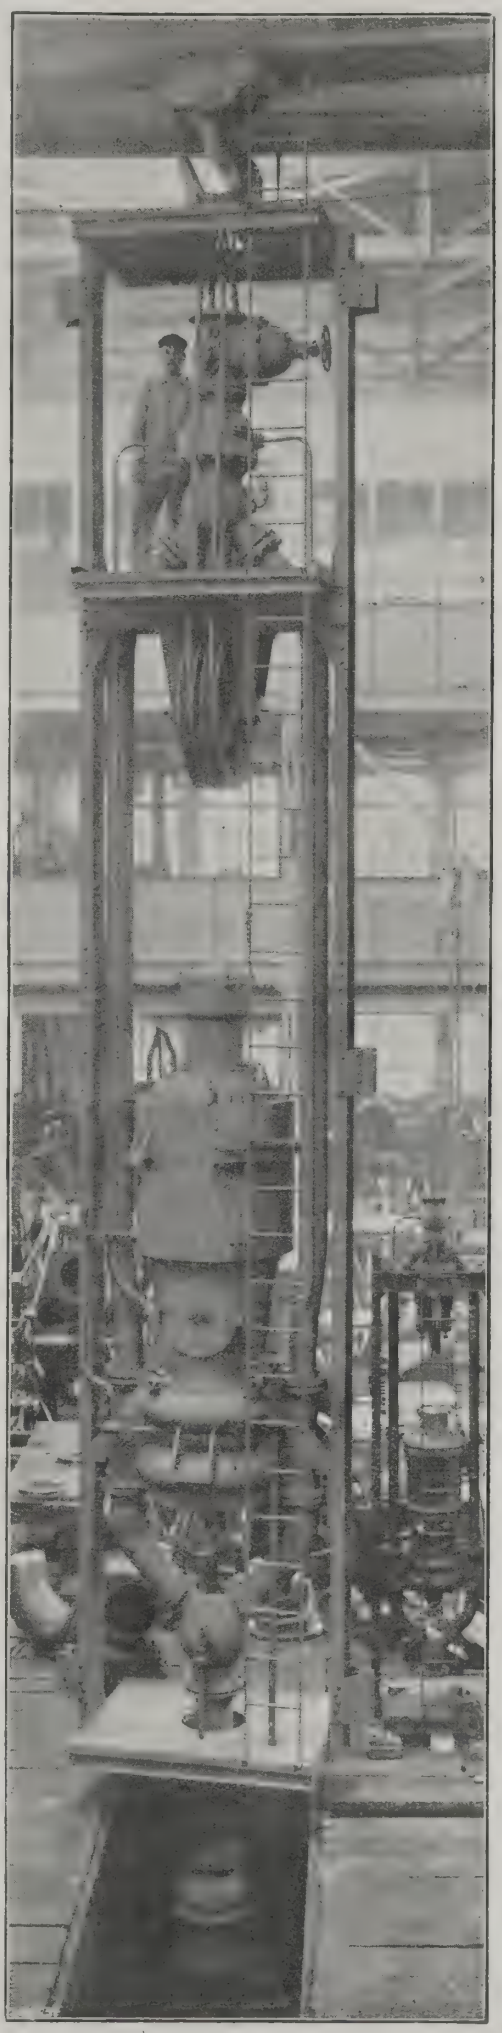

FIG. 22. SINKING PUMP BEING ERECTED.

The works as they now stand were commenced in 1834 by the putting down of a foundry. There are now, as will be seen in the plan, Fig. 1, three cast-iron foundries; these cover a total area of 28,500 sq. m. (34,000 sq. yards). Their annual output amounts to 20,000 tons of castings, and they employ, as stated above, 1400 men. In many engineering works, both in this country and on the Continent, the foundry is frequently considered as a very secondary shop, and, in [illegible]veral instances, no very special care seems to have been given to its installation. At Messrs. Sulzer's Works, on the contrary, the foundry has always, from the very commencement, been looked upon as forming

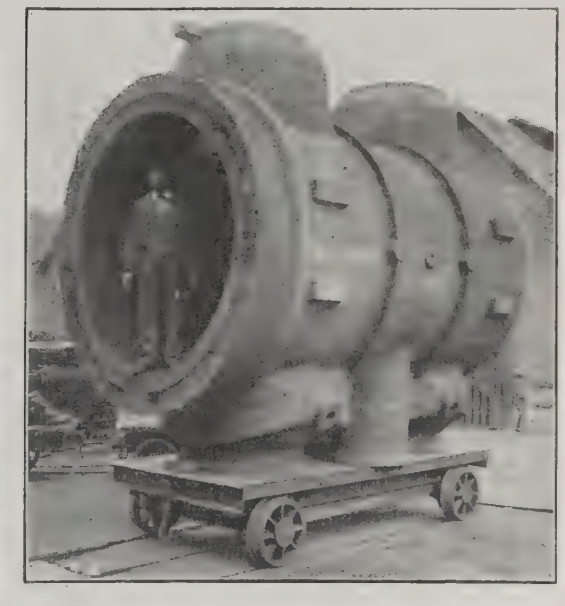

FIG. 25. LOW-PRESSURE CYLINDER FOR A 6000-HORSE-POWER STEAM-ENGINE FOR MOABIT POWER-STATION, BERLIN.

the principal shop. The foundry, as it were, forms a separate and privileged part of the establishment. It has its own special organisation, and is not under the supervision of a works manager, but under that of one of the Brothers Sulzer, and this has always been the case. The present partner who has charge of the foundry department is Mr. Albert Sulzer, who succeeded to the senior partner of the preceding generation, Mr. Sulzer-Grossmann; the latter managed it during forty-three years—from 1867 to 1910. The work in the foundry has always been carried out on the best scientific methods. The chemical and physical laboratories, besides the analyses and research work they make concerning all the material used throughout the shops—nickel-steel, other alloys, paints, lubricants, and so forth—are very fully occupied in testing the raw materials used in the manufacture of the different castings, and also specimens of the casts. Most of the coal and pig iron used by Messrs. Sulzer comes from this country. They turn also to account various grades of scrap and briquettes made of the chips collected from the fitting and machine-shops.

In Winterthur and the neighbourhood, Messrs. Sulzer's works have always been, and are still, known and referred to as the "Giesserei," the foundry.

The foundry for light work, shown in the views, Figs. 4 and 5, on Plates XIV. and XV., was put down in 1873, and enlarged in 1894. It is built of iron and glass exclusively, and is admirably lighted and ventilated. It covers an area of 6300 sq. m. (67,800 sq. ft.), and is divided into four

bays, served by sixteen overhead electric travelling cranes, ranging from 1 to 15 tons. Most of the work is done by moulding-machines. It contains five cupolas of Sulzer design and construction, with fore-hearth, each cupola having a capacity of from 3 to 6 tons per hour. A complete system of railway tracks run throughout the shops, and special frame cars, which can be seen in the view, Fig. 4, are used for the rapid removal of castings and machinery parts. An annexe to the foundry contains the core-making and the sand-mixing machinery. This latter is on two floors, the upper one containing the mixers, the grinding-machines, and also a series of magnetic separators. The fettling-shop consists of two special annexes which communicate with the hand-moulding section, and contains two fettling-tables, three fettling-drums, sand-blast apparatus, emery and sand wheels. All the dust from the fettling-tables and apparatus is exhausted by vacuum.

The foundry for heavy castings covers, including the fettling-shop, the drying-ovens, and the sand-mixing plant, an area of over 7200 sq. m. (77,500 sq. ft.). Special care has, as we have stated, been taken to ensure perfect lighting and ventilation of the shop. It is served by 18 overhead travelling-cranes, worked electrically, and ranging from 5 to 25 tons; two 2-ton hand travellers; one electric 2-ton jib-crane; two 2-ton lifts; and 24 different hand-cranes of 1, 2, and 3 tons capacity. It contains five large cupolas, with fore-hearths, each cupola having a capacity of 5 to 9 tons per hour; the fore-hearth connected to each cupola has a capacity of from 8 to 10 tons. The sand and loam-mixing machinery is on the south side of the foundry, and is of the most approved type. There are six casting-pits up to 6 m. (19 ft.) in diameter, and of various depths. The drying-ovens are fourteen in number, distributed throughout the foundry, and mostly used for drying cores. The moulds themselves are dried by portable fires, supplied with air-blast in the usual way. The largest piece cast weighs 40 tons. The foundry for heavy castings is illustrated in the views, Figs. 6 to 8, on Plate XV. The fettling-shop is in the rear of the cupolas, and, as will be seen from Fig. 9, on Plate XVI., is most carefully designed with a view to the removal of all dust. The latter is received in a number of grated openings on the floor level, connected to an underground gallery which ends in a common dust-collector. The sand removed from the castings is carried out by an hydraulic lift. Fig. 10, on Plate XVII., illustrates a similar installation in connection with the foundry for light work.

Messrs. Sulzer Brothers manufacture in very large numbers complete heating plants for dwelling houses and all classes of buildings; these require a very large quantity of castings, such as radiators and other parts. The manufacture of all these castings is centralised in a separate shop, shown in the plan, Fig. 1, which is served by sixteen cranes of 12 cwt. to 4 tons. These details of heating plant being a speciality which is quite distinct from the others with which the firm deals, the section of the works devoted to it forms a department to itself. A view in the radiator foundry is given in Fig. 11, on Plate XVIII.

The brass foundry is shown in Figs. 12 to 14, on Plate XVIII. It has two characteristic features. In the first place, it occupies the upper storey of a two-storey building; it is further, we believe, the largest brass foundry on the Continent to belong to an engineering works which does not make a speciality of the supply of brass castings as such. Messrs. Sulzer use a very large quantity of brass-work of different grades in their various manufactures, especially, perhaps, for their pumps, and they have always endeavoured to remain completely independent of outside sources, and to be able to undertake absolutely all responsibility for the whole of the work they supply; in this they have hitherto fully succeeded. The brass-foundry building covers an area of 900 sq. m. (9700 sq. ft.). The ground floor and the first floor are set apart for sand-mixing, offices, and stores. The second floor, forming the foundry, contains four Piat-Baumann crucible furnaces, two of 4 cwt. and two of 6 cwt., and two other smaller furnaces. The floor of the foundry is occupied by the moulding frames; an adjoining room is set apart for fettling, and in this, as in the cast-iron foundries, the dust is exhausted by vacuum. Access is had to the foundry by steps; it is also served by an hydraulic lift. This arrangement is conductive to the saving of floor-space. The foundry being on the top of the building, it is possible to utilise the floors below, whereas the gases from the foundry would make it impossible to erect offices and stores above it. The arrangement has further made it possible to have the foundry in a central position, close to all the other shops to which its products have to be distributed. Our views, Figs. 12 to 14, show the upper floor above the ground floor, occupied by the foundry.

Before describing the other shops we may refer here to the power-stations in the works. These stations are three in number, distributed as shown in the plan, Fig. 1, Plate XIV. At the present time electricity is used almost exclusively for power transmission. Formerly it was used only for lighting, and in 1878 small dynamos were put down throughout the works as they then stood for supplying current to arc-lamps. The first generating-station for power was built in 1894; this supplied 250 horse-power to hoisting apparatus and ventilating-fans, there being at that time twenty-eight electric motors in the various shops. A second station was put down in 1895. Connected to the three main stations there are three sub-stations for light and power; the capacity of the total plant for power and lighting is 2900 horse-power. The generating-station near the smithy contains a 400 horse-power vertical compound steam-engine running at 100 revolutions; this drives by belting a part of the lathes in the turnery. The vertical steam-engine in question was exhibited by Messrs. Sulzer at the Paris Exhibition of 1889; we described it at the time (ENGINEERING, vol. xlviii., page 488). The main generating-station is close to the boiler-shop. This contains a 1300-horse-power 1500-revolution Sulzer steam-turbine, direct-coupled to a Brown-Boveri three-phase generator which supplies a 3000-volt 50-period current; this high-tension current is transformed down to 200 volts in part in the generating-station itself and in part in one of the sub-stations. The same generating-station contains also a 600 to 800 horse-power horizontal steam-engine running at a speed of 150 revolutions, being an old compound engine which has lately been transformed for experimental purposes into a uniflow steam-engine. This horizontal engine is direct-coupled to a 200-volt 50-period electric generator.

We may mention here that the current which Messrs. Sulzer can now generate at their works in their three stations is in excess of their requirements, and experiments have repeatedly been made with the horizontal engine just mentioned. The last-named generating-station is, in fact, used at the present time also as a testing-room for steam consumption and so forth. A few years ago these two generating-stations became inadequate, and the constant development of the works rendered necessary a further supply of power. In the meantime, Messrs. Sulzer having improved the design and construction of Diesel engines, they decided to build a third station and to equip it with these motors. This third station is close to the foundry for heavy castings, and lies opposite to the second one. It contains a 350-horse-power and a 150-horse-power motor, both four-cycle, and direct-coupled to 200-volt three-phase fly wheel generators. The larger Diesel engine has a speed of 140 revolutions, and the smaller one a speed of 180 revolutions.

The steam supply is ensured by three boiler-rooms containing in all nineteen steam-boilers. The boiler-room in close proximity to the station containing the turbine and uniflow engine has eight boilers, with automatic stoking and automatic coal delivery, two being water-tube boilers, one a Garbe tubular boiler, the five others being Cornish boilers. A boiler-room near the boiler-shop contains a boiler having 340 sq. m. (3660 sq. ft.) heating surface. The one near the large foundry contains a boiler having 210 sq. m. (2260 sq. ft.) heating surface. The steam that can be raised in these three boiler-rooms is more than sufficient for the present requirements, and gives an ample margin for further extensions.

Near the main boiler-house and power-station is the smithy. This measures 41 m. (134 ft.) in length and 26 m. (85 ft.) in width, and contains eight steam-hammers, varying in power from 5 cwt. to $3\frac{1}{2}$ tons, served by open fires and by nine revolving cranes. The heaviest forgings turned out weigh from 5 to 6 tons. The smithy is an accessory shop, since a large number of forgings of special shapes, or of weights exceeding the above maximum, are obtained from outside sources, either rough machined or simply in the forged state.

Close to the smithy is the turnery; the heavier machines are on the ground floor, and the lighter on the upper floor. As early as in the 'fifties and 'sixties of last century Messrs. Sulzer were able to design and to build for their own exclusive use quite a number of machine and other tools of different types for special classes of work, and this placed them quite early in the day in a favourable position for the manufacture of any given class of plant or machinery. They were thus easily able to maintain in their own hands a monopoly for the products in question. Not only so, but the reputation which Messrs. Sulzer have since acquired in reference to the high finish of their engines and various machines can in a very great measure be traced to the fact that they very early built in their own works the appliances to manufacture them. They continue to work on the same lines, and still design and build any special machine-tool they may from time to time require for the carrying out of particular work. The turnery contains an excellent plant of modern machinery; the building itself, however, is one of the oldest in the works.

Adjoining the power-station, which contains the turbine and horizontal engine, is the pump-testing room for testing all pumps up to those having exceptionally large deliveries. The pump-delivery measuring-tank can be fitted with a series of changeable outflow discs, a method which was introduced by Messrs. Sulzer, and which is now generally followed.

Near this testing department is the former delivery bay, which has since been transformed into an erecting-shop for pumps and steam-turbines. It is illustrated in Fig. 15, on Plate XIX., which shows a 10,000-horse-power Sulzer turbine in the background.

From this shop, which is located at the extreme eastern end of the works, the centre of the establishment is reached through the turnery and a small fitting and erecting-shop for parts forming heating installations, adjoining which the large fitting, erecting, and testing-shop for Diesel engines, ammonia-compressors, pumps, and other machines, has been built. The department for the construction of heating installations (the parts forming which are cast in the separate foundry, called the radiator foundry, already dealt with) is one of the very busy departments at Messrs. Sulzer's works. For these installations they are now putting down at Ober-Winterthur, a distance of about three miles, a special building to maintain the fitting and erecting of radiators as distinct as possible from their other manufactures. This new building, above referred to, and the framework of which is illustrated in Fig. 3, on Plate XIV., will be complete in itself, and will contain its own power-station. It will comprise, besides a large wood dépôt, a wood-drying plant, frame-saws, and the briquetting-presses for briquetting the chips for use in the foundry cupolas.

The boiler works, located to the south of the engineering shop, consists of the copper-smithy, the tube and pipe-bending shops, and the large boiler-shop proper, which runs parallel to the Swiss Federal Railways. Fig. 16, on Plate XIX., is a view inside the boiler-plate-bending and machining-shop, and Fig. 17, on the same plate, illustrates a number of boilers erected in the works, and ready for delivery. The boiler-shop communicates with the plate-bending, flanging, and drilling-shop. The plates are bent by vertical rolls. Autogenous welding is used extensively. Messrs. Sulzer build their boilers complete with every fitting and accessory without exception, and are thus able to readily undertake all the required guarantees and responsibility. All the brass fittings proceed from their brass foundry. The firm have been known for years past almost exclusively in connection with their steam-engines with their special valve distribution, but their boilers have been, and are still, much more extensively distributed over the world than even their engines have been, and they have always proved, at least, quite as satisfactory in every respect as the latter.

In connection with this portion of Messrs. Sulzer's Winterthur establishment, it is interesting to notice that the works also have been fully busy since 1860 with the manufacture in the usual way of shrapnel shell for use by the Swiss Artillery Corps. The shells are finished ready for firing by the Swiss arsenal at Thun. One of the early Sulzer Brothers spent several months in the late 'fifties of last century at Woolwich Arsenal, and there decided to take over this speciality at Winterthur; since then the Winterthur Works have supplied the Swiss artillery with shrapnel shell at different intervals.

In Fig. 18, on Plate XIX., we illustrate the

delivery bay. This delivery department, as alluded to above, was formerly in another part of the works, but was transferred to its present position a few years ago. It is a model of its kind and has invariably excited the admiration of visitors. An annexe to this forms the radiator dépôt and contains a very large number of these ready for delivery. A large number of buildings and sheds, not numbered in the plan, Fig. 1, placed at convenient sites, contain the various stores and dépôts.

The large fitting and erecting-shop, which we illustrate in the views, Figs. 19 to 21, on Plates XX. and XXI., is built of armoured concrete. It measures 80 m. (262 ft.) in length, and 72 m. (236 ft.) in width. Taken cross-wise, from east to west, it is divided into four smaller bays, having galleries at top, and three large glazed bays, there being a smaller bay between the left-hand and the central one, and also between the central and the right-hand one. This is an

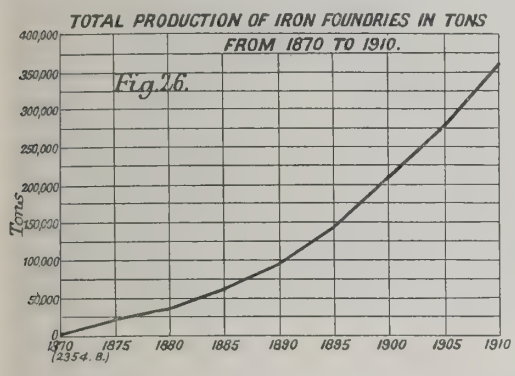
All the engines are tested on the beds in the shop on which they have been erected; they are made to run for eight days consecutively. The power is recorded by a Heenan and Froude hydraulic brake. The exhaust gases are led to silencers and to pipes placed outside the west wall of the shop, the pipes being led up to the roof. Messrs. Sulzer have already built, including the 16,060 horse-power above given, a total of about 140,000 horse-power to the present day.

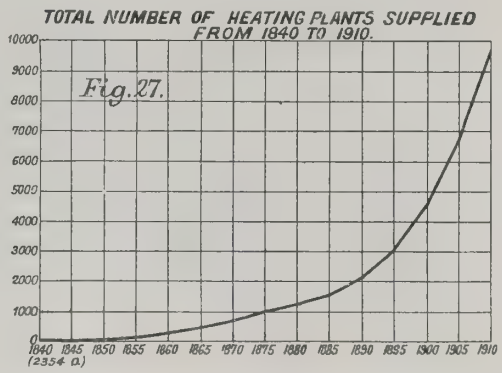
Close to the delivery bay is the shipbuilding shop, used at the present time—in the temporary absence of contracts for passenger and other steamers for navigation on the lakes—for working up plates and section work. The plates and frames forming the ships' hulls are bolted together at the Winterthur Works, then riveted up in the Navigation Companies' slips on the lake shores.

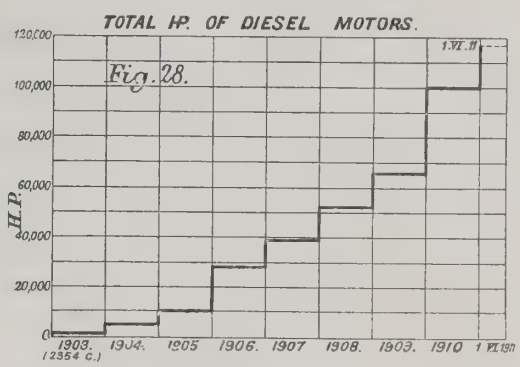
In proximity to this shop is a testing station in

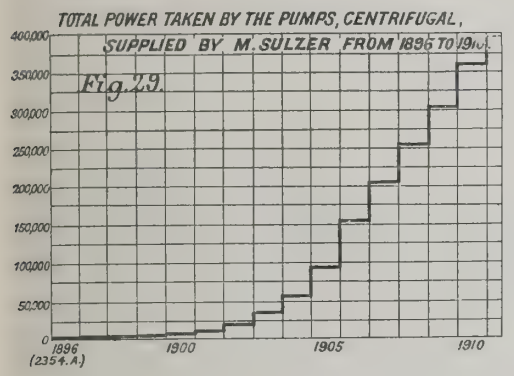
low-pressure cylinder for a 6000-horse-power steam-engine for a current-generating station.

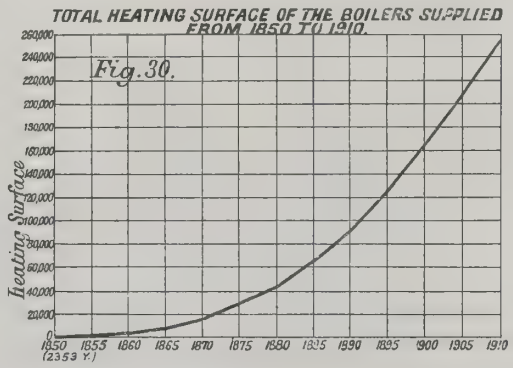
The curves, Figs. 26 to 32, on the present page, illustrate better than any description the gradual development of the works at different periods. These curves show the total production of the iron foundries in tons from 1870 to 1910; the total number of heating plants supplied from 1840 to 1910; the total horse-power of Diesel engines built from 1903 to June 1, 1911; the total power required by the pumps supplied from 1896 to June 1, 1911; the total heating surface of the boilers built from 1850 to 1910; the total horse-power of the steam-engines built from 1855 to 1910; and the number of workmen and staff from the earlier days, 1834, down to 1910. The whole of these curves, it will be noticed, rise constantly, although every year of the time they cover cannot have been equally prosperous all round. They give

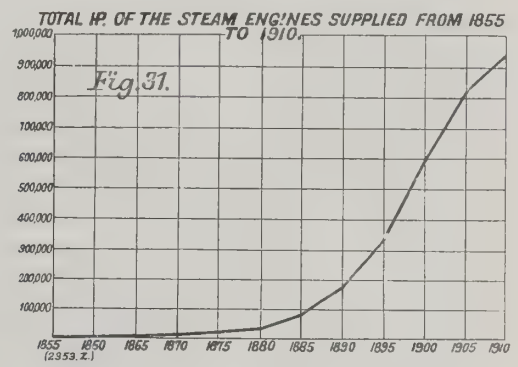






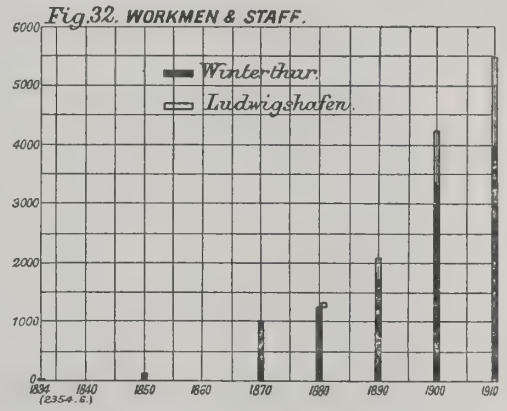






admirable shop, most carefully lighted and ventilated; it is heated during the winter months. An idea of its height is afforded by the view, Fig. 22, on page 83, which represents a sinking pump in course of erection. The galleries over the four smaller bays are served by lifts; access is also had to them by double sets of stairways. They are set apart for bench-work, small machining-work, assembling detail parts for Diesel engines, and for erecting small engines and pumps. Under the first, left-hand, or east, glazed large bay are large machine-tools, crank-shaft lathes, plate lathes, transportable machine-tools, a large planing and milling-machine capable of machining pieces measuring 15 m. (50 ft.) in length and over 2 m. (6 ft. 6 in.) in diameter, and weighing up to 30 tons. Under the adjoining smaller bay the pumps are erected, and the larger parts and mechanical details for the Diesel engines are fitted together. The large central glazed bay forms the erecting-shop for large stationary Diesel engines and pumps. In the smaller bay, separating the central bay from the right-hand, third, or west, glazed bay are erected the Diesel marine motors. The third large glazed bay, like the centre one, forms an erecting-shop for large stationary Diesel engines. The last small bay under the gallery is the erecting-shop for high-speed Diesel engines. Each of the three large bays, with glazed roof, is served by a 30-ton and a 20-ton overhead electric travelling-crane. The four smaller bays under the gallery have two 5-ton electric travellers each; in some a 15-ton traveller is substituted for a 5-ton one. At the present time Messrs. Sulzer have in this building in course of erection, or in process of testing, the following Diesel engines:—

Stationary:	Thirty-four engines, for a total of 11,460 horse-power	Total: 16,060 horse-power.
Marine:	Ten engines, for a total of 4600 horse-power	



which Messrs. Sulzer propose to carry out a series of exhaustive tests with a Diesel locomotive on which they have been working since 1905. We understand that they are making excellent progress in this direction, and we hope to be able to deal further with the subject later on.

The firm have also worked most actively at the development of Diesel engines for marine purposes, and have already built a good number of these for sea-going boats, including submarines; they have in hand at the present time a set of Diesel engines for an ocean steamer. They are proceeding with their experiments in this direction without remission, and are at the present time carrying out a complete series of experiments with a 2000-horse-power two-cycle cylinder with a view to battleship propulsion.

Fig. 23, on Plate XXI., which represents a water turbine-wheel cast in one piece by Messrs. Sulzer Brothers, gives an idea of their skill in foundry work. Fig. 24, on the same plate, shows a heavy centrifugal-pump casing weighing 25 tons on the lathe in their turnery. Fig. 25, on page 83, is a

an unmistakable indication of a perfect organisation, of a thrifty management, and of a satisfactory reserve fund.

The men employed at Messrs. Sulzer's works are almost all on piecework, only a few being on day-work. They are paid fortnightly. The shop methods are very generally on the "American system." A special office settles the piecework prices; the men are satisfied, and work with a will; in fact, we have hardly ever come across a better and a more contented-looking set of artisans. The reason why there is no labour problem at these works is that the owners were years ago able to solve the almost insoluble problem which consists in taking a fatherly care of the men while remaining their master. They have also and for many years taken care to train the men's sons, both practically and technically, in the trades for which the boys felt a special vocation, and have thus and for many years developed their own staff. Like a few other Swiss works, they exclude absolutely workmen of several other nationalities, and thereby they continue year in and year out to live in peace.

The school for the boys is just outside the works; this was the original shop and offices, first built in 1834. Special interest attaches to this building. At one time it had been decided to do away with it to make room for necessary extensions. Considering, however, that it formed, as it were, the old stem on which had grown the works as they now stand, and in which a preceding generation of Sulzers had expended their energies, it was removed and rebuilt, stone by stone, unaltered, on the site it now occupies. To it Messrs. Sulzer have added a canteen, a reading-room, and baths for the men. A proof of the men's standard is afforded by the fact that the library and reading-room are exceedingly well attended. Dwellings have been built for the men. Each man who has been employed at the works for a period of at least ten

years receives one week's holiday every year, his wages being paid him during the time. Life insurance and invalidity funds have been established for many years, and work most satisfactorily.

The very complete and accurate account-keeping, with which a separate statistical bureau is entrusted, makes it possible for the owners and their staff to obtain at any time an exact idea of the progress of the work being carried out in every department. Each machine-tool has its own account, and the work carried out with it is credited to it for amortisation. A standardising bureau sees that, when this is in the least degree possible, all pieces have to be manufactured to standards, for which patterns, jigs, &c., are available.

This thorough organisation in every detail; the total absence of unnecessary staff and "fausses manœuvres" which, unfortunately for them, are to be met in so many other establishments; the regard which the men feel, and very justly so, for the owners, have made it possible for the latter to compete with success in every part of the world with the works of other nations eminently more favoured from the point of view of raw material and other physical facilities. Nor do the firm confine their activity to the specialities already referred to, for they also take a strong interest in important civil engineering works, a fact of which their share in the construction of the Simplon Tunnel affords a striking example.

THE WORKS OF MESSRS. ESCHER WYSS AND CO., ZURICH.

THE works of Messrs. Escher Wyss and Co., at Zurich, which will be visited by the members of the Institution of Mechanical Engineers on Tuesday next, the 25th inst., may be said to constitute the cradle of the Swiss mechanical engineering industry. They were founded as early as 1805, by Hans Kaspar Escher. Like many young men who have made for themselves in later years a name in the metallurgical and engineering world, H. K. Escher was destined by his parents for a different career; it had been decided in the family circle that he should be a merchant. He entered commercial life, but this for him was drudgery, and he soon left it to devote his energies to architecture. Owing, however, to the unrest which generally reigned in the early years of the 19th century, architecture could hardly be made to pay, and there was "nothing doing" in that profession.

It was during a period of slackness in his architectural work that H. K. Escher had his attention called specially to mechanics. Switzerland had long been known for some of her hand-made light textile fabrics. The report had reached Escher that there were then working in this country a number of cotton-spinning machines which were greatly successful, so much so in fact that their manufacture and their use were kept absolute secrets. He immediately saw the advantages which would be derived by the construction of such machinery in Switzerland. He came to this country, where he managed to see the machinery in question, he got out drawings of similar machines from memory, and returned to Zurich, where, in 1805, he built the Neumühle works on the Limmat, the river formed by the outflow from Zurich lake. These works were able to put their first mechanically-spun yarn on the market in the commencement of 1807. The Escher Wyss Co., founded in 1805, primarily for spinning, very shortly afterwards added to their work the building of the machines for outside buyers, and gradually the company was transformed from a spinning concern into one engaged in the manufacture of spinning machinery. Their engineering specialities, however, gradually increased in number, and included, as the years went by, the construction of water-wheels, transmission gear, steam and water-heating installations, machine-tools, grinding-mills, stationary steam-engines, and steamers complete. H. K. Escher died in August, 1859, and the works management was continued by members of his family and others who had been his collaborators in the earlier days of the company, or who had joined it subsequently. In 1889, the concern was transformed into a share company. In the meantime the business of the firm had increased to such an extent that new premises had to be taken, there being no space available at Neumühle to allow for expansion. A tract of land was selected in the north-western part of the city, on which the first shops of the present works were built in 1895.

The general arrangement of the works is shown in the plan, Fig. 1, annexed. They are admirably laid out, the various shops and offices covering an area of 35,000 sq. m. (41,800 sq. yards) of the total site, which has an area of 90,000 sq. m. (107,000 sq. yards). One of the principal specialities of the company at the present time is the construction

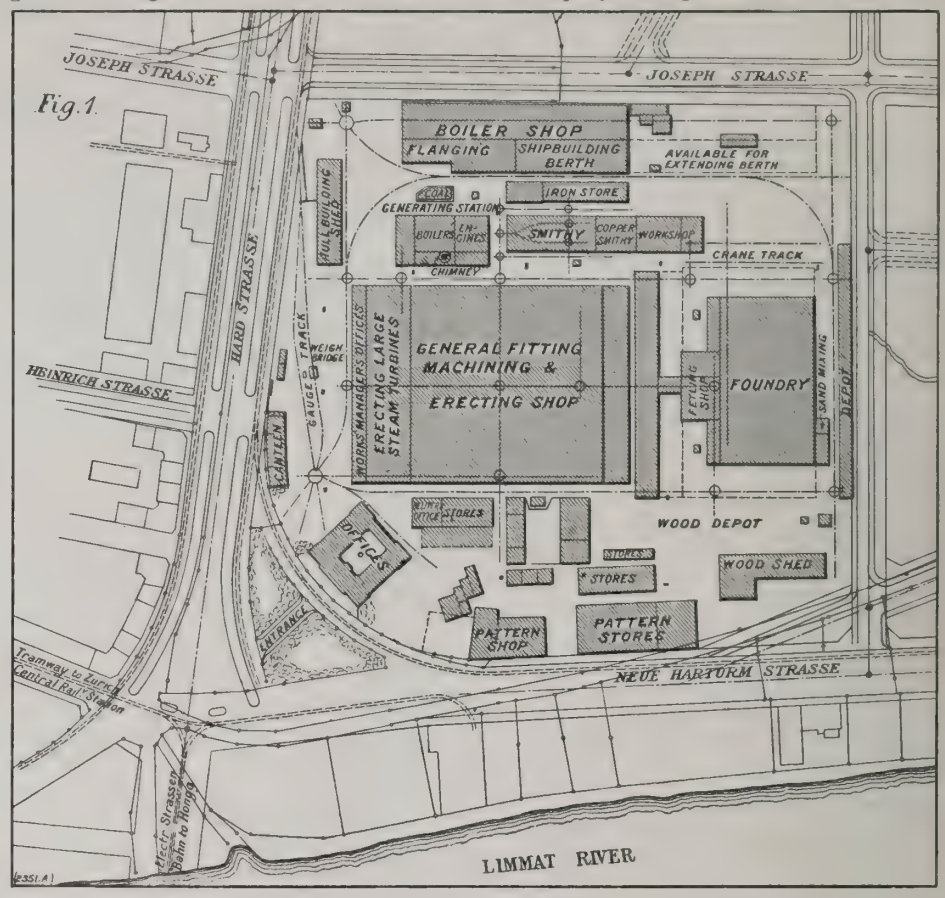


FIG. 1. PLAN OF WORKS.

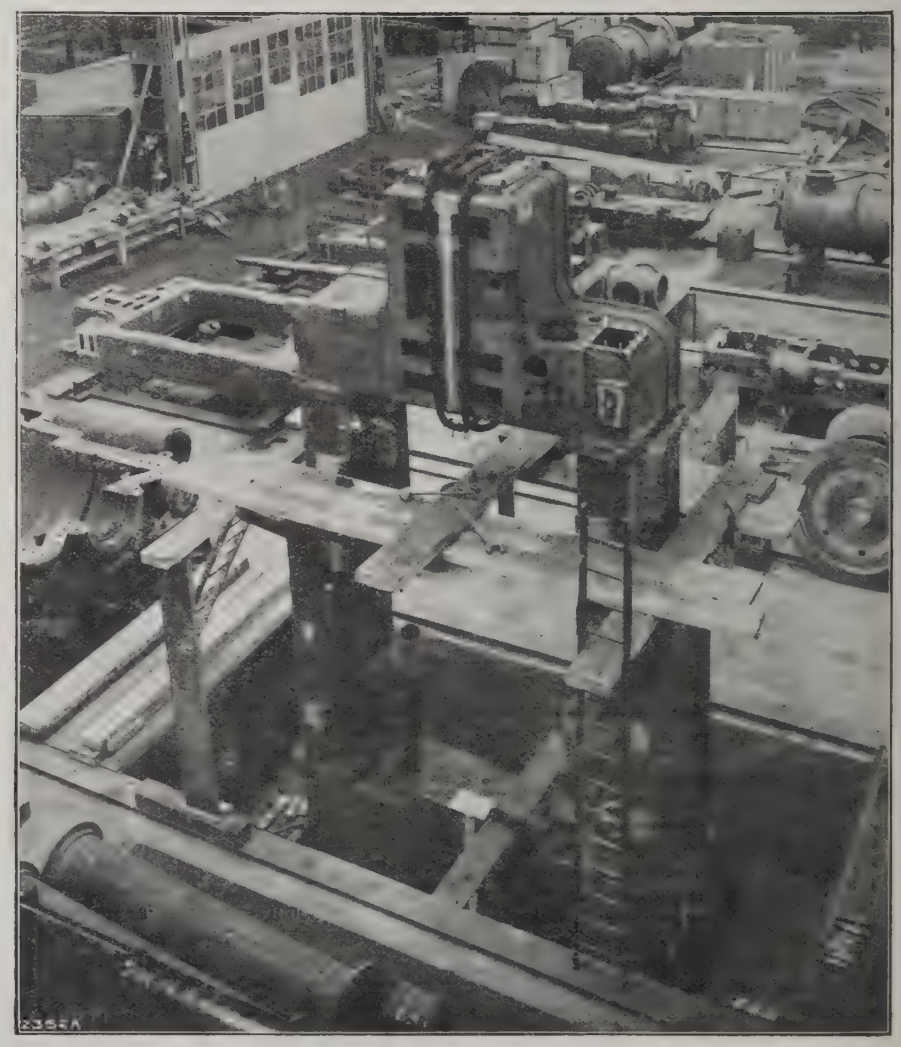

FIG. 26. VIEW SHOWING METHOD OF ASSEMBLING BED-PLATES VERTICALLY.

of water-turbines and water-power installations complete, of which they have built a very large number of all powers, for all purposes, working

under the most varied conditions, and under heads up to 910 m. (2986 ft.). Up to June last they had either built or had in course of construction :—

2611 tangential wheels, for 994,229 effective horse-power,
2282 Francis turbines, for 1,008,682 effective horse-power.
Total 4893 water-turbine plants, for 2,002,911 effective horse-power, and
5200 m. (over 32 miles) of high-pressure conduits.

They also build the Zoelly steam-turbine for all powers, ranging from 10 to 10,000 horse-power, and have supplied among other large units :—

One 7500 horse-power, 1000 revolutions, for the Central Station, Reisholz (Germany) ;
One 7500 horse-power, 1500 revolutions, for the Centrale Electrique de l'Escaut ;
One 5000 horse-power, 1400 revolutions, for the Charbonnage Grand Hornu (Belgium) ;
One 8500 horse-power, 1500 revolutions, for the Hydro-Electrica Española, Madrid.

The firm also design and build refrigerating machinery and installations, paper-making machines, steamers for lake navigation, steam-driven motor-boats complete, pumps and pumping installations complete, and Zoelly turbo-compressors. We will now proceed to give a brief description of the works.

The pattern-shop, in close proximity to the offices, is a two-storey building 40 m. (130 ft.) in length and 22 m. (72 ft.) in breadth, equipped with the necessary wood-working machinery, the wood chips and sawdust being exhausted from each machine. Close to this is a three-storey building, measuring 65 m. by 26 m. (213 ft. by 85 ft.), containing the pattern stores.

The foundry, which is illustrated in Figs. 2 and 3, on Plate XXII., is a clean, healthy shop, well equipped, and from which the smoke and gases are carefully exhausted. It is 88 m. (288 ft.) in width and 34 m. (111 ft.) in length, divided into seven bays, an annexe containing the brass foundry, another the sand-mixing plant, and still another the necessary appliances for the manufacture of cores. On leaving the foundry, and on their way to the machinery and erecting building, the finished castings pass through the fettling-shop. The brass foundry measures 37 m. by 7 m. (120 ft. by 23 ft.) The whole of the foundry installation covers an area of 5680 sq. m. (6800 sq. yards). The cast-iron foundry is served by twelve overhead electric travellers of powers ranging from 5 to 20 tons. It contains three cupolas, having a capacity of 3, 4, and 5 tons per hour. Most of the work is cast in sand, but the foundry is fully equipped for casting in loam ; the largest pieces, for water-turbines, are mostly so cast, and weigh up to 20 tons. The brass foundry contains eight Baumann crucibles, and can exceptionally manufacture pieces weighing up to $2\frac{1}{2}$ tons.

The machine and erecting-shop for steam-turbines and water-wheels occupies the centre of the works and is a magnificent shop. It is illustrated in Figs. 4 to 24, on Plates XXII. to XXVII., and is 145 m. (575 ft.) in width and 104 m. (340 ft.) in length, divided into fifteen bays, as follows :—One of 8 m. (26 ft.), one of 23 m. (75 ft.), six of 13 m. (42 ft.), six of 4 m. (13 ft.), and two of 6 m. (19 ft.). The whole of the bays are served by eighteen overhead electric travelling-cranes, of power ranging from 5 to 30 tons. The largest, 23 m. (75 ft.), bay contains four travellers, two of 10 tons, running on a track situated at a height of 7.5 m. (24 ft. 7 ins.) above the shop level, and two of 20 and 30 tons, on a track at a height of 10.5 m. (34 ft. 5 ins.) above the same level, and therefore above the smaller ones. Normal and narrow-gauge railway tracks run throughout the building from all the other shops ; railway wagons can be loaded for the delivery of finished machinery by the overhead travelling cranes in the different bays. A marked feature of this building is the method followed for heating it during the winter months, when the outside temperature remains for many weeks together below freezing point. The heating installation consists of eleven hot-water boilers, which supply hot water through pipes which are fitted vertically, parallel with several of the columns supporting the various bays, or through a system of radiators, which are mounted inside the built-up stanchions in the centre bays (see Figs. 8, 9, 10, and 13, on Plates XXIII. and XXIV.). The heating of the shops commences with the setting in of winter and continues night and day without interruption until spring ; it costs the company 30,000 francs (1200*l.*) every winter.

The large machine-tools are driven electrically by separate motors ; the medium-size and smaller ones are driven electrically in sets by belt transmission. There are, so to speak, no specialised machines ; they are employed indifferently on water-turbine or steam-turbine parts, or for machining the elements of other plants manufactured by the firm. There are several large and powerful tools, among which we may mention a vertical boring and turning machine capable of taking pieces up to 2.6 m. (8 ft. 6 in.) high and 4 5 m. (14 ft. 9 in.) in diameter, and next to it a similar machine taking pieces having the same height and up to 6 m. (19 ft. 8 in.) in diameter. Close to these, and distributed over the shops, are twelve marking-out tables. The work coming from the foundry, in a straight line through the fettling-shop, is delivered to these marking-out tables, whence it proceeds to the machining department, to that machine suitable for the work which happens to be free to take it, thence it passes to the erecting bay. This large shop may be considered as

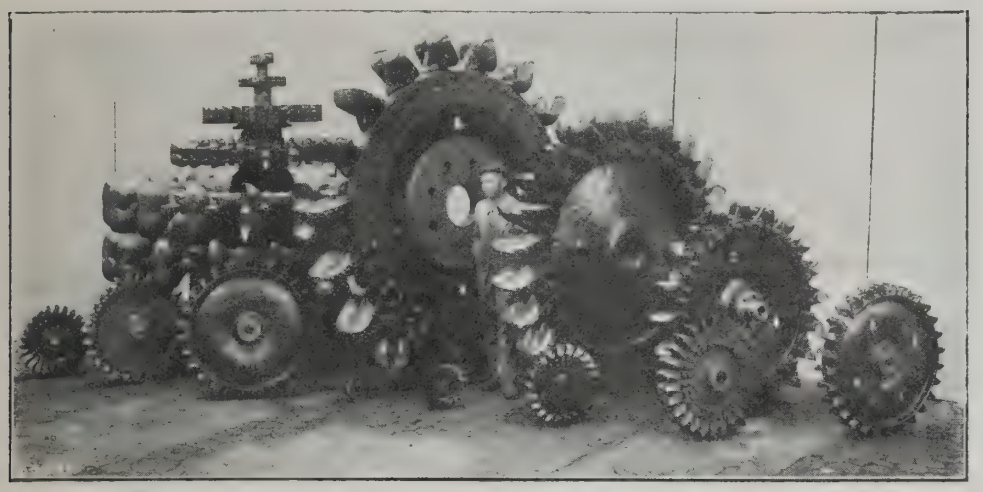

FIG. 27. PELTON WHEELS.

FIG. 28. PADDLE-STEAMER LOADED FOR TRANSIT.

FIG. 29. MOTOR-BOAT LOADED FOR TRANSIT.

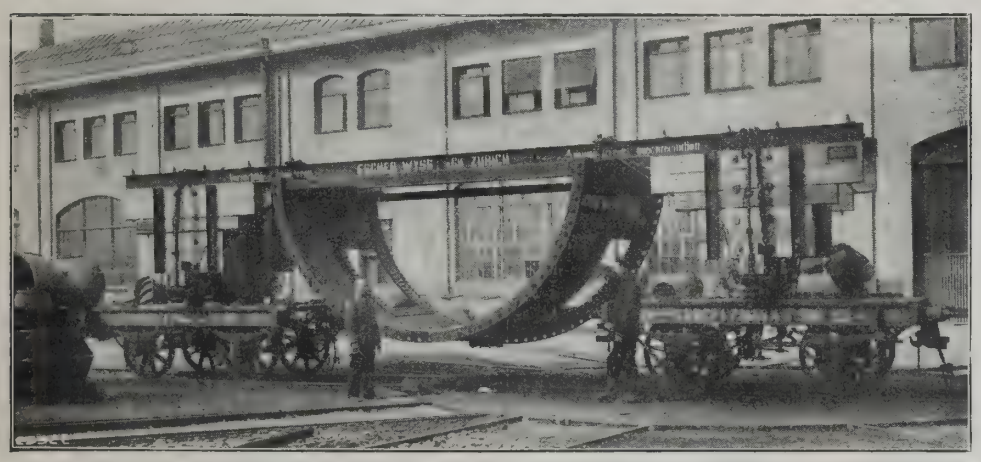

FIG. 30. HALF-CASING FOR WATER-TURBINE.

divided into two parts by the railway track through its centre; on one side are located the machine-tools, while on the other side is the erecting department for the various machines and installations built by the firm. The large bay contains at the present time in course of completion and testing under steam the following large steam-turbine units: one of 8400 horse-power at 1500 revolutions, one of 5000 horse-power at 1500 revolutions, one of 3000 horse-power at 1500 revolutions, and one of 7300 horse-power at 1500 revolutions, besides a large number of smaller turbines.

The steam-turbines are erected on heavy framework built over a number of separate masonry pits, several of which are provided with live steam flexible connections for supplying steam to any turbine under test. The pits are also provided with the necessary connections with the condensing plant, with lubricating pipes, and all the necessary apparatus.

The water-turbines are erected in the same bay, when space is available, and also in two of the parallel bays. Messrs. Escher Wyss and Co. have lately completed and delivered two 13,000 horse-power 225 revolutions 160-ton turbines to work under a head of 33 m. (108 ft.). They have in course of construction for the Laufenburg, Switzerland, hydro-electric generating station, four water-turbines of 5000 horse-power each, for an 8 m. (26 ft. 3 in.) head; six 12,500 horse-power units for Japan, for a head of 120 m. (393 ft.); six 12,000 horse-power units, also for Japan, for a 320 m. (1050 ft.) head; besides a number of other smaller units. They have also recently booked a contract from the Rio de Janeiro Tramway, Light, and Power Company for two water-turbines each of 19,000 horse-power, for a head of 266 m. (872 ft.). These will be the largest water-turbines yet built in Europe. Escher Wyss water-turbines are now working in practically every country of the world.

A portion of the main engineering building is set apart for a tool shop; the company generally manufacture all their special tools, most of which are of high-speed steel or with high-speed steel insets.

The boiler-shop, flanging-shop, and ship-construction berth, measures 120 m. (393 ft.) in length, 36 m. (118 ft.) in width, and is served by three overhead electric travelling cranes, two of 15 tons and one of 5 tons. Fig. 25, on Plate XXVII, is a view in the boiler-plate-bending shop. The shipbuilding berth is closed on the outside by a movable partition to allow for extension. Messrs. Escher Wyss and Co. have at the present time on order two passenger steamers for Lake Constance and Lake Neuchatel. The principal dimensions of these steamers are the following :—

—	Length.	Beam.	Power of Steam-Engines.
			h.-p.
Lake Constance	53.5 m. (175 ft.)	6.3 m. (20 ft)	700
Lake Neuchatel	46 m. (150 ft.)	6 m. (19 ft.)	350

Their hulls will be bolted up on the shipbuilding berth at the Zurich works, then taken to pieces for riveting on the slipways belonging to the Lake Navigation Companies, where the steamers will be launched, engined, and fitted up. At the present time the berth is occupied by a barge, which Messrs. Escher Wyss and Co. are building for a contractor for service on one of the Swiss lakes. It is built in two longitudinal parts, which are taken apart for delivery by rail, the two parts will be finally riveted up together on the spot. The barge is propelled by a screw, driven by a 15 horse-power petrol motor. In the boiler-shop proper are several large boilers in course of completion, including a tubular boiler for a passenger steamer for Belgrade, Servia, for which the firm are also building the 700-horse-power steam-engine; several condenser-shells, &c. A large hydraulic riveting-machine, which is capable of taking pieces up to 3.5 m. (11 ft. 6 in.) in diameter and 10 m. (32 ft. 10 in.) high, completes the installation.

The smithy is 48 m. (157 ft.) in length and 18 m. (59 ft.) in width; it contains five steam-hammers of from 2 to 30 cwt. served by the necessary open fires and revolving-jib cranes. The copper-smiths' shop, which adjoins the smithy, deals with the bending of pipes of various diameters required in the different installations built by the company.

A good view in the turbine-erecting bay is afforded by Fig. 26, on page 86, which shows their method of erecting bed-plates for turbine sets vertically in one of their turbine-erecting and testing pits. Fig. 27, on the same page, shows a number of Pelton wheels manufactured by the firm.

Messrs. Escher Wyss build a large number of motor-boats complete, fitted with a multitubular-boiler arranged to burn coal, oil fuel, or wood, and supplying steam to miniature marine-engines, which they build, of powers ranging up to 100 horse-power. They have several small shops set apart for this, and have at the present time in course of construction for Brazil, a steam-driven yacht, the hull of which is built of galvanised-steel sheets. She is 20 m. (65 ft. 7 in.) long, 2.5 m. (8 ft. 2 in.) beam, and 1.1 m. (3 ft. 7 in.) deep, and with wood-firing will reach a speed of 24 km. (14.9 statute miles), with 50 horse-power. Fig. 28, on page 87, shows a small steam paddle-boat, 59 ft. long, in three sections, ready for delivery. Fig. 29, on the same page, illustrates a 25-horse-power steam-launch for a Swiss lake.

Fig. 30, also on page 87, shows the manner followed for delivering the housings for large water-turbines.

There are distributed over the works and in convenient situations a number of store rooms and dépôts, as shown on the plan, Fig. 1.

The current-generating station is parallel with the main central building and in a line with the smithy. Messrs. Escher Wyss and Co. own at Bremgarten, on the Reuss, at a distance of about 12 miles from Zurich, a 1500 horse-power hydro-electric station, from which they take 900 horse-power in the form of three-phase current at 5000 volts, the remainder being sold to other firms. The 5000-volt three-phase current is transformed down to 200-volt three-phase at the Zurich works station for power. This station contains three steam-boilers, having a total heating surface of 620 sq. m. (6600 sq. ft.), and provided with superheaters and economisers. They supply steam to three engines, two being vertical, of 250 and 350 horse-power, and one horizontal, of 450 horse-power, thus aggregating 1050 horse-power, coupled to the electric generators. The electric lighting throughout the works is by continuous current, generated by the 350 horse-power vertical-engine set. The boilers supply the steam and superheated steam to the turbines undergoing their steam tests in the erecting-shop above referred to. They are fed with water from a well sunk in close proximity. The draught is obtained by a brick chimney 40 m. (130 ft.) high, provided at about the middle of its height with a water-tank having a capacity of 50 cubic metres (11,000 gallons), into which the water from the well is pumped for delivery to various parts of the works and offices. The steam-engines in the works' generating station act as a stand-by and run more generally during the winter months, when there is not sufficient water at the Bremgarten hydro-electric station. Two small locomotives are used for hauling cars to and from the various shops.

We have stated above that Messrs. Escher Wyss and Co. have built water-power stations for heads up to 910 m. (2986 ft.). A recent installation of theirs of considerable importance is that of the Adamello, on the Austro-Italian frontier, in which the water from the lake of Arno is utilised in a generating-station at a place called Isola. Further extensions of the system are contemplated. The power-house at Isola has been designed for seven sets of 6500 horse-power each, consisting of Pelton wheels 2.750 m. (9 ft.) in diameter, coupled to 12,000-volt three-phase generators.

The Zurich works employ 2000 engineers, clerks, and men. Messrs. Escher Wyss and Co. also own works at Ravensburg, in Germany, which employ 300 men in the construction of water-turbines, paper-making plant, and transmission gearing.

THE PORT OF DAKAR.—The French authorities are showing much energy in the development of Dakar, the capital of the French possessions in Western Africa. Large sums have in the course of the last two years been expended upon harbour works, and the entrance is now protected by two piers carried a considerable distance out to sea. The dry dock, which has entailed an expenditure of about 125,000*l.*, can accommodate vessels up to 16,000 tons capacity, and is practically the only dock on the West Coast of Africa. During the last eight years an aggregate of about 2,000,000*l.* has been expended in public works of different nature, and a still larger sum is available for further undertakings, canals, waterworks, &c.

LITERATURE.

Bridge Engineering—Roof Trusses: A Manual of Practical Instruction in the Calculation and Design of Steel Truss and Girder Bridges, for Railroads and Highways, including Analysis and Design of Roof Trusses and other Details of Mill Building Construction. By FRANK C. DUFOUR, C.E.; Assistant Professor of Structural Engineering, University of Illinois. Chicago: American School of Correspondence; London: Crosby Lockwood and Son. [Price 12s. 6d. net.]

THIS book, primarily designed for the use of students of the American School of Correspondence, is not to be regarded, it may be presumed, as complete in itself, since it is intended for the use of those who are to profit also by assistance rendered by the school. It is to be expected, therefore, that the treatment should be somewhat less convincing than in the case of a work entirely self-contained. This proves to be the fact, yet though the statement of principles is somewhat bald, and in some cases not free from obscurity, and no sort of demonstration of those principles is, as a rule, vouchsafed, the methods are so fully detailed that the student may hope by diligent application and much thinking, to arrive at a sound understanding of the reasons underlying the processes developed; but for the unaided reader it will hardly be an easy book. Those having some knowledge of the subject, being less dependent upon extraneous help, may find the book useful as a means of recovering lost knowledge, or of supplementing that already mastered.

Of some 250 pages devoted to bridge engineering, about one-half are allotted to the determination of stresses in framed structures, by usual algebraic methods, graphic solutions being in no case resorted to. Various cases of loading are dealt with, and the solution of maximum web and chord stresses for concentrated wheel loads is given in considerable detail for the simpler forms of trusses and for plate girder-spans. Wind effects are treated at some length, both with respect to through and portal bracing, in an instructive manner. The latter part of the space devoted to bridge engineering is used to give practical expression to the teaching of the earlier part, by dealing with detail design and methods of construction in steel. This portion is perhaps more satisfactory than that which precedes it; there is much information of value in design, and though presenting nothing very new, yet, by collecting useful matter from diverse sources, the author renders no little service to the student. Examples of a plate girder bridge and of a through Pratt truss-span are worked out at length. Before dismissing this section of the book it may not be improper to note that the title is a little too inclusive, having regard to the fact that a small part only of the whole science of bridge engineering is treated, and some idea of the limitations of this part will be gathered from the fact that though treating of steel construction wholly, the flexure of beams and trusses is nowhere touched upon

The second section of the book, of nearly 100 pages, dealing with roof trusses, contains much information of a very practical kind, and is perhaps on the whole superior to that dealing with bridges. A collection of formulæ for the weights of roof trusses, by various authorities, is displayed, giving, however, very divergent results. With respect to these formulæ it may be said that Merriman's, though simple, appears to be, in its results, most conformable to British practice, while Bryan's seems to be incorrectly given in this connection, as it yields weights sufficient, indeed more than sufficient, to include both the truss and all other steel-work of one bay. The loads to be supported by roof trusses, recommended for adoption, are in excess of those commonly assumed in this country, due, no doubt, to differences of climatic conditions as to a great part. The calculation of inclined rafters, as given in one of the examples, in which no notice is taken of the effect of inclination upon the bending effort of vertical loads, is hardly satisfactory.

With respect to the very usual practice of computing stresses in ordinary roof trusses by assuming an inclusive distributed and vertical load, instead of determining such stresses correctly for the various conditions of loading, the author, commenting upon it, approves the usage for spans up to 100 ft., though it is doubtful if it can wisely be adopted beyond 60 ft., at about which width differences in the approximate and the true stress values, and the sections resulting, begin to be appreciable. Reversal of stress in some members, due to wind striking the

roof on one side, may also become a serious matter if the vertical load convention be too light-heartedly adopted. The treatment of stresses in the main members is indeed of a somewhat perfunctory character. The many short cuts to stress amounts, though undeniably helpful in practical design, are not such as to develop in the student a mastery of the subject. Some cases of difficulty have, however, received particular attention, as in the case of roof trusses connected by knee-braces to wall stanchions, for which the stresses are investigated at length. The details of roof construction and roof coverings are exceptionally full and instructive, and should prove of the greatest utility.

As a whole, this book has much to recommend it. It will be most useful to those who are already well advanced in this branch of study, or to those others who are well tutored while working through the volume. The illustrations are good.

BOOKS RECEIVED.

Lehrbuch der Elementaren Praktischen Geometrie (Vermessungskunde). Band I. *Feldmessen und Nivellieren, des Lehrbuchs der Vermessungskunde Besonders für Bauingenieure.* Von Dr. E. HAMMER. Leipzig and Berlin: B. G. Teubner. [Price 22 marks, unbound; 24 marks, bound.]

The Production of Malleable Castings: A Practical Treatise on the Processes Involved in the Manufacture of Malleable Cast Iron. By RICHARD MOLDENKE. Cleveland, Ohio: The Penton Publishing Company. [Price 3.00 dols., express prepaid.]

The Design of Channels for Irrigation or Drainage. Compiled by ROBERT BURTON BUCKLEY, C.S.I. London: E. and F. N. Spon, Limited; New York: Spon and Chamberlain. [Price 2s. net.]

BROUGHTON DYE WORKS, SALFORD BOILER EXPLOSION.—We are informed that the formal investigation ordered by the Board of Trade to be held in this matter is fixed for hearing in the Town Hall, Broughton, Salford, Lancs., on Tuesday, the 25th inst., at 11 a.m.

THE SWISS LOCOMOTIVE AND ENGINEERING WORKS, WINTERTHUR.

IN the late 'sixties of last century, an important development took place in the Swiss railways; the railway companies increased the number of their lines, strengthened their permanent way, and planned further extensions of their systems, for which they obtained, very generally, the assistance of the towns and districts traversed. At that same period, various classes of steam-engines and other machinery were being built in the country, and Swiss machinery users were gradually becoming more and more independent of outside sources for the prime movers they required. In respect of locomotives, however, they were absolutely dependent upon foreign works, no home works having as yet laid themselves out for their manufacture. The development referred to in railway construction led to the formation of the Schweizerische Locomotiv- und Maschinenfabrik; this was established in 1871, at Winterthur, with a share capital of 1,200,000 francs (48,000*l.*) and a debenture capital of 600,000 francs (24,000*l.*), the object in view being the construction of locomotives, and also of other types of engines. The works were opened on July 1, 1873. In the commencement, the company had to fight against very great odds. In the first place, the capital was far too low, considering the programme it had set to itself; the cost of the buildings and plant exceeded the figures calculated, owing to a rapid increase in the cost of material and labour; the boom in trade and industry which followed upon the Franco-German war was of much shorter duration than had been expected; stagnation in business rapidly supervened and prices fell all round owing to over production. The new enterprise in its early days was practically unable to withstand the competition of the German locomotive builders; these were long-established firms, favourably located both in regard to the supply of materials and the delivery of finished products, eager for an extension of their business and under the fostering care of the German State. Another factor which greatly handicapped the new Winterthur locomotive works was the very low duty paid on foreign locomotives on their entrance into Switzerland, compared with the duty charged by other neighbouring countries.

The company passed through several crises before the 'eighties, when it was established upon a firm basis, with a share capital of 8,000,000 francs (320,000*l.*), and a debenture capital of 3,000,000 francs (120,000*l.*). Since that time the Swiss Locomotive and Engineering Works has prospered; all the large Swiss railway systems, the secondary railways, and the mountain lines have gradually contracted more and more with this company, which now supplies the greater part of their requirements in the matter of locomotives. Not only is this the case, but the firm has become a serious competitor to the locomotive works of other countries, and an idea of its activity is afforded by the fact that it has built and supplied to date, besides a total of 1470 locomotives for the Swiss railways, 607 to other European countries, including 157 to Italy, 103 to France, 92 to Germany, and six to this country; and, further, 113 to distant lands. The company builds locomotives of all types and powers; it has also made a speciality of the construction of rack-railway engines, and has likewise built a comparatively large number of electric locomotives.

The company took in hand, in 1886, the construction of internal-combustion engines, since which time it has greatly increased its production in gas oil, petrol, and alcohol motors. It commenced with town-gas motors, it then dealt with producer-gas installations complete, and has added to these, in comparatively recent times, the Diesel engines, which it builds of powers ranging from 20 to several hundred horse-power, under an agreement with Messrs. Sulzer Brothers, whose works are adjoining.

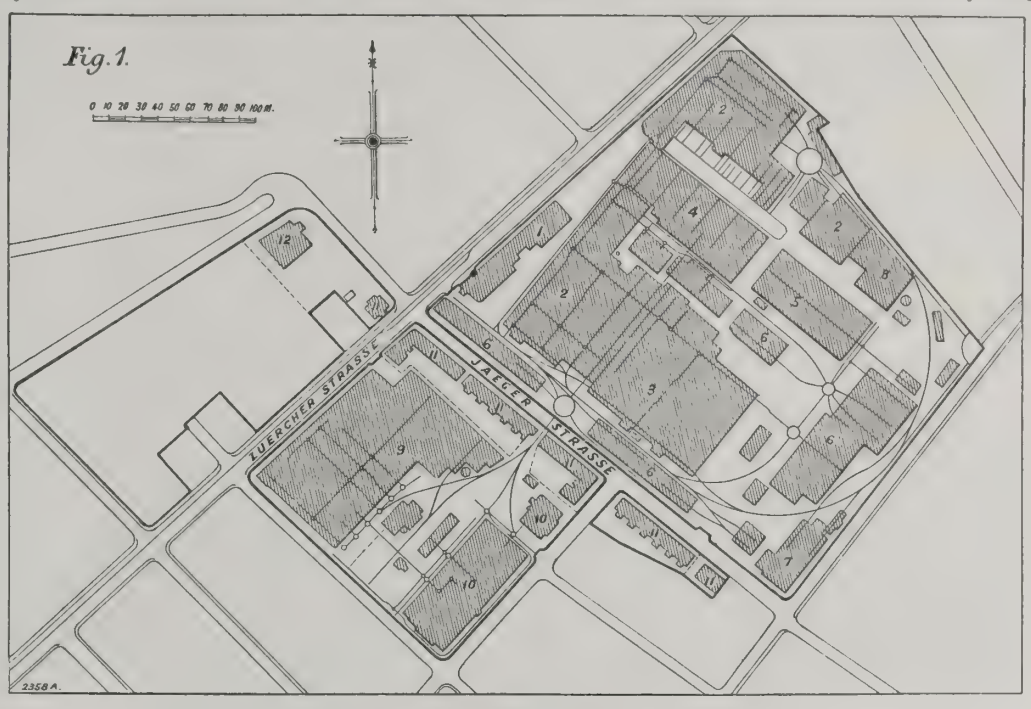

FIG. 1. PLAN OF SWISS LOCOMOTIVE WORKS.

At the present day, the works, which will be visited by members of the Institution of Mechanical Engineers on Wednesday next, the 26th inst., give employment to 1500 men. They cover an area of 89,462 sq. m. (over 100,000 sq. yards), and their arrangement is shown by the plan, Fig. 1, annexed. The references to this plan are as follow:—

1. Offices.
2. Locomotive fitting-shops.
3. Tender and boiler-shops.
4. Locomotive - erecting shops.
5. Smithy.
6. Stores.
7. Delivery department.
8. Generating - station for light and power.
9. Internal - combustion-engine shops.
10. Foundries.
11. Dwellings for fire brigade.
12. Workmen's club and canteen.

The works are divided into two main parts by the Jaeger Strasse, the portion to the east containing the offices and the shops for the construction of locomotives, locomobiles, stationary engines, and boiler work; the portion to the west being set apart for the construction of internal-combustion engines. Fig. 2, page 90, is a general view of the works; Figs. 3 and 4, on Plate XXVIII., are views in the locomotive-erecting shop, and in the erecting and testing-shop for internal-combustion engines, the two principal shops on either side of the works.

Dealing first with the locomotive section, the stores for raw material and other products required throughout the works are contained in two large buildings, measuring 60 m. (197 ft.) in length and 9 m. (29 ft.) in width, close to the entrance and parallel with the Jaeger Strasse. The fitting and machine-shop for all the mechanical parts required in the construction of locomotives, marked 2 on the plan, contains a great variety of machine-tools, driven by belting from overhead shafts, the grinding-machines being provided with exhausting apparatus for carrying away the dust. The side closer to the offices is occupied by fitters' benches. A great proportion of the machine-tools in this department are semi-automatic, and are arranged in sets, each set being supervised by one man. The tool-shop and tool-stores is in the centre of

this machine-shop; it contains all the tools, gauges, and jigs used throughout the works, among which are several very fine sets of milling-cutters. This shop is driven by a 170-horse-power horizontal steam-engine, which drives the overhead transmission shafts by belting. The shop is in direct communication with the tool-manufacturing departments, which consist of a smithy and an installation for hardening and tempering the different tools, which are manufactured of carbon, high-speed, and other quality steels. The hardening and tempering installation was designed and built by the company, and is considered the best-equipped installation for this class of work in the whole of Switzerland. All the furnaces in this installation are heated by producer-gas, and a temperature up to 1300 deg. Cent. can be reached. Close to this is the building set apart for case-hardening motion links and blocks, this containing three furnaces, which are heated either with coke or with producer-gas.

Adjoining the fitting and machining-shop is the tender and locomotive-boiler shop, which covers an area of 4800 sq. m. (51,700 sq. ft.). It is shown in the view, Fig. 5, on Plate XXIX.; it is divided into five bays; of these, there are two newer bays on the south-east end of the shop, east end of the works is well equipped. It contains the following sets:—(1) A 400-horse-power double-acting horizontal tandem producer-gas engine, driving a 300-kw. 400-volt three-phase alternator. (2) A 300-horse-power double-acting horizontal single-cylinder producer-gas engine, driving by belting a 200-kw. 400-volt three-phase alternator. (3) A 200-horse-power single-acting horizontal tandem producer-gas engine, driving by belting a 150 kw. 400-volt three-phase alternator. (4) A 150-horse-power single-acting horizontal double-cylinder producer-gas engine, driving by belting a 100-kw. 400-volt alternator. These four engine sets supply current for power purposes throughout the works. Besides these there are:—Two 100-horse-power single-acting horizontal single-cylinder producer-gas engines, driving by belting a 75-kw. 120-volt continuous-current dynamo for lighting.

The whole of the above engines are supplied with gas from a battery of six Dowson pressure-producers, three of which are being replaced by suction-gas producers. This producer-gas power-station for power and light was commenced about fifteen years ago; it has gradually been increased to meet the growing needs of the works. It is interesting inasmuch as it affords an illustration of the different types of gas-engines built during the period in question, and of the progress made in their construction.

The locomotive frames are machined and built up in a separate shop adjoining the electric power-station; this shop is divided into two bays, and contains in the centre a number of machines for dealing with frame-plates. Each bay is served by a 10-ton overhead electric travelling-crane. Power for driving the machinery is supplied by a 50-horse-power crude-oil engine (Winterthur system), which drives the machine-tools in the shop by an overhead shaft; close to this engine on the floor level and driven by a belt from the overhead shaft is an alternating-current generator, which acts as a stand-by.

The locomotive-erecting shop, marked 4 on the plan, Fig. 1, is divided longitudinally into two bays, served by 20-ton and 30-ton overhead electric travelling-cranes. There are in this shop in course of construction at the present time locomotives for the Swiss railways, for the Paris-Orleans Railway Company, for the Northern of France Railway Company, for the Santa Fé (Argentine) railways, and a number of trucks for electric mountain railways. Outside this shop and parallel with it is the traverser-track for carrying the locomotives to the painting-shop. A shop for manufacturing the small fittings and containing the copper-smithy communicates with the locomotive-erecting shop.

The above is a brief description of the locomotive section of the works, which contains besides all the requisite store-houses, dépôts, &c., located at convenient sites. As above stated, the Jaeger Strasse separates this department from the internal-combustion engine section. The latter is bounded on the street end by a series of forty dwellings, marked 11 on the plan, Fig. 1, each dwelling being let to a family. These dwellings are let at low annual rentals to foremen and workmen employed in the various shops, who elect to serve on the works' fire-brigade. These dwellings are very neat, and are most carefully kept. When a vacancy occurs in any one of them—and a vacancy rarely occurs except through the death of the occupant—numerous applicants are forthcoming for the vacant dwelling notwithstanding the exigencies of the fire-service, or rather the ties necessarily associated with this service, for fires occur, fortunately, but very seldom.

This section of the works may be said to consist of two main departments: the foundries and the fitting and erecting-shop for the internal-combustion engines. The brass foundry, a building measuring 20 m. (65 ft.) in length and 20 m. in width, contains two Piat-Baumann crucible furnaces, each of

FIG. 2. GENERAL VIEW OF THE SWISS LOCOMOTIVE AND ENGINEERING WORKS, WINTERTHUR.

65 m. (213 ft.) in length and 30 m. (98 ft.) in width, served one by a 25-ton overhead electric travelling-crane, and the other by a 15-ton similar crane, these two newer bays being set apart for the assembling of locomotive boilers and fire-boxes. The boiler-shop contains all the necessary machines for working up the plates which enter in the construction of locomotive engines, including hydraulic riveting machines, the newest of which can take plates 7 m. (23 ft.) in length and 3 m. (9 ft. 10 in.) in diameter. Pneumatic riveters are also used to a very large extent. Motive power is supplied to the boiler shop from an adjoining room, which contains a 100-horse-power four-cycle crude-oil engine (Winterthur system), which drives the machine shaft by a steel belt transmission. The room also contains two hydraulic pumps working at a pressure of 100 atmospheres (1400 lb. per sq. in.), which supply the accumulator for working the hydraulic riveting machines, stamping presses, and so forth. Oxy-acetylene blow-pipes are used extensively for cutting out openings in boiler and furnace plates.

The smithy, marked 5 in the plan, Fig. 1, is a building 70 m. (230 ft.) in length and 30 m. (98 ft.) wide, divided into a central bay and two side bays, and containing a 1.5-ton hammer, served by a reheating furnace, with a hand-crane close by. There are also eight smaller hammers, served by two other furnaces, and forty-two open fires.

The electric power-station in the extreme north-a total capacity of 4 cwt., and one ordinary melting furnace. The fettling-shop is adjoining.

The cast-iron foundry is a well-lighted building 80 m. (262 ft.) in length and 35 m. (114 ft.) wide, divided into three bays, the main central bay being served by two overhead electric travellers of 15 tons, and the other bays by eleven cranes of different sizes. The foundry employs two hundred men, and is principally occupied with the manufacture of castings used in the construction of internal-combustion engines. All the work is cast in sand; the weight of the largest piece cast is 24 tons. There are three cupolas, one having a capacity of 5.5 tons, and the two others a capacity of 3.5 tons each per hour; the foundry contains also three drying-stoves, and a number of portable drying-fires supplied with blast from special fans. The largest pieces are cast in the central bay, the smaller work and accessory foundry work being carried out in the side bays.

The newest shop in the whole installation is that marked 9 in the plan, Fig. 1, which is set apart exclusively for the machining, fitting, and erecting of internal-combustion engines. The company commenced building producer-gas engines and plant complete in 1895; previously they had made a speciality of the construction of town-gas engines, having commenced building these, as above stated, in 1886, concurrently with locomotives, which latter have always formed their principal speciality. In

this shop the "American methods" of working are followed, and every detail of the engines is standardised. The various machine-tools are driven from six electric-motors in the shop, supplied with current from the works' generating-station above described; should this current supply fail through any cause, current would be supplied to the motors from the municipal current generating station. There is also a 100-horse-power two-cylinder vertical gas-engine for driving the machine-tools. Overhead belt transmission is resorted to generally for this. The machine-tools are of the most approved types.

This fitting and erecting-shop, views inside which are afforded by Figs. 6 to 8, on Plate XXIX., is covered by a saw-tooth roof and is divided crosswise into ten bays, served by fifteen overhead electric travelling-cranes ranging in power from 3 to 25 tons. One side of the building is made with a gallery, which contains the hand-fitting benches. The tool-store is in the centre, as is also the dépôt of working drawings for all detail parts, the drawings being delivered out to the men as required, and against a check. A room underground is set apart as a stores for manufactured parts and for accessories and fittings purchased from the outside.

The works build both gas and Diesel engines on order, or for stock, and they are always able to give quick delivery. They have at the present time in course of construction about 160 engines of different types, which include:—(1) One and two-cylinder horizontal Diesel engines; one to four-cylinder vertical Diesel engines, ranging from 25 to 300 horse-power. (2) Town and producer-gas engines, horizontal, single-acting, with one or two cylinders, from 6 to 300 horse-power; and vertical, from 70 to 600 horse-power. (3) Current sizes of petrol and oil-engines (4) A series of small crude-oil "Winterthur" engines of 5 to 20 horse-power. (5) Different sizes of gas-producers for the corresponding engines.

All the engines are tested on the bed upon which they have been erected; a special building contains the producer-gas plant for testing the producer-gas engines. The Diesel engines are tested regularly during ten consecutive hours after erection and previous to taking down for delivery. A very complete chemical laboratory is equipped for analyses; analyses and tests of coal for use in the producers are the most numerous.

This very brief description of the Swiss Locomotive and Engineering Works Company would be incomplete without a passing reference to the workmen's club and canteen—or "casino," as it is called—marked 12 in the plan, Fig. 1, and illustrated in the views, Figs. 9 and 10, annexed. This is admirably equipped with reading-rooms, dining-rooms, a kitchen with two large coppers for making coffee, to serve out to the men in the works during the summer months.

The building contains under the floor level 50 cells for douche baths, which the men use against payment of 1d., for which they receive a piece of soap and the use of a towel. There are, besides, three bath-rooms, the price for using which is 3d. Several of the upper rooms are equipped for use by the doctor, who calls regularly twice a week for consultation. Surrounding the casino, as shown in plan, Fig. 1, is a tract of land which is let out to the men for allotment gardens. During the last ten years benevolent institutions, pension and invalidity funds, have been founded by the company in favour of their men.

FIG. 9. EXTERIOR VIEW OF CASINO.

FIG. 10. INTERIOR VIEW OF CASINO.

NOTES FROM THE UNITED STATES.

PHILADELPHIA, July 12.

THE weather has been exceptionally oppressive for over a week, resulting in some stoppages in mills and partial stagnation in some lines of trade. A number of blast-furnaces have blown out because of slow distribution, and this has to some extent lessened coke consumption. General trade is up to the summer average. The month's output of pig iron made from anthracite and coke was 1,787,566 tons. The daily rate of production was 59,585 tons, the lowest since January. The total output of pig iron for the half-year was 11,630,054 tons, as against 12,319,807 tons last half of last year, a decline of 5 per cent. The repairing season is now on, and rolling-mills will gradually resume. Prices in all crude and finished products are unchanged. Very few buyers care to extend deliveries beyond the end of the third quarter. The spread of railroad construction in the North-West calls for corresponding machine-shop facilities, and this is reflected in a better inquiry for shop tools and equipment, as well as for electrical equipment. Water-power is being secured in various sections of the United States and Canada, and plans are being perfected for the erection of electrical plants for the generation and transmission of power for varying distances.

The demand for structural material for railroad and general construction purposes is improving, the June aggregate being 128,000 tons; the May aggregate, 180,000 tons; and the April aggregate, 90,000 tons. The next encouraging demand is for agricultural steel. Usually implement manufacturers buy in May or June for a year ahead, but this year they have delayed until July, and their orders are helping to give a stronger tone to the agricultural steel industry. Other branches are dragging along with a demand pretty near normal for the time of year. Twelve thousand workmen are still on strike at the Baldwin Locomotive Works in this city. The company is booking orders freely, evidently anticipating an early resumption. The intense heat all over the agricultural States has not as yet done any harm to crops.

THE BRITISH ASSOCIATION.—The British Association will this year assemble at Portsmouth on August 30, and the meeting will last the customary week and one day, concluding on the following Wednesday. It will be the first time that Portsmouth entertains the Association; Sir William Ramsay will preside. It is expected that general discussions will again be encouraged. The Engineering Section G will have a joint discussion on "Mechanical Flight" with Section A, Mathematics and Physics; a similar discussion was held last year; this year the subject is to be opened by Mr. A. E. Berriman. In its own deliberations Section G, under the presidency of Professor J. H. Biles, will discuss the Advantages of Superheated-Steam-Engines (Captain H. Riall Sankey), of Suction-Gas Plants (Mr. Tookey), and of Diesel Engines (Mr. C. Day); the names in brackets are those of the gentlemen who are to open the discussions. As regards sh pping, papers will be presented by Mr. G. K. B. Elphinstone, on the "Gyro-Compass;" by Mr. B. P. Haigh, on "Electrical Steering;" by Mr. H. A. Moor, on "Electrical Driving of Ships' Propellers;" and by Mr. J. H. Rosenthal, on "Marine Engines for Burning Crude Oils." Mr. Digby will describe the vibrograph; Mr. Worby Beaumont will speak on the origin and production of corrugation on tramway rails; and Dr. J. S. Owens will discuss smoke abatement. Radiotelegraphy will also be dealt with; Captain Sankey is expected to exhibit a portable radiotelegraphy equipment, and Professor T. W. Howe will show some novel experiments on radiotelegraphy. In accordance with our custom, we shall publish further particulars of the arrangements made for the British Association in the week preceding the opening of the meeting.

INDUSTRIAL NOTES.

THE monthly report of the Amalgamated Tool-Makers for July shows an increase of 975 in the membership since June, 1910. The number of unemployed for June last was the same as in the corresponding month of last year—namely, 81—and the reserve funds stood at 22,500*l.*, against 16,500*l.*—an increase of 6000*l.* The total membership now stands at 5184.

The return for the four weeks ending July 1 shows a total membership of 3171 in the Associated Blacksmiths and Ironworkers' Society, against 3187 for the previous month, or a decrease of 16. The income for the four weeks in June last was 737*l.* 10s. 5½d., and the expenditure 532*l.* 7s. 2½d., a net gain of 205*l.* 3s. 3d. The outlay for the four weeks for benefits and management came to 3s. 8d. per member. The amount of the expenditure was made up as follows:—Unemployment benefit, 51*l.* 17s. 7d.; superannuation benefit, 167*l.* 5s. 10d.; sick benefit, 132*l.* 6s. 9½d.; funeral benefit, 29*l.*; management outlays and grants, 160*l.* 17s. Wages have been advanced 3s. per week in the Clan Line repairing shops, in the Glasgow Co-operative Baking Society ½d. per hour, and in the Clyde Trust and Messrs. A. W. Smith's ¼d. per hour, but trouble seems to threaten with the Belfast employers, who have declined to grant a conference. The trade in the shipbuilding industry continues good, and there is a good demand for labour, while on the engineering side of the industry work is plentiful; altogether the outlook is said to be promising.

According to the monthly report of the United Society of Boilermakers and Iron and Steel Shipbuilders for July, the number of members signing the book at the end of June was 2017, as against 1486 at the end of May last. There were 941 members on the sick fund, compared with 1210 at the end of May, and 2124 on superannuation, compared with 2400 in the previous month. The expenses for June amounted to 6956*l.* 8s. 5d., against 6054*l.* 15s. for May, or an increase for June of 901*l.* 13s. 5d. There were, however, five weeks' expenses in June against four in May.

According to the Board of Trade *Labour Gazette*, issued on July 17, the state of the labour market in June was as follows:—

Employment continued good, but was not quite so good generally as in May. There was a slight improvement in the pottery trade and at iron and steel works, but in most other industries, except mining, employment declined slightly. Some trades were adversely affected by the woolcombing and shipping disputes.

As compared with a year ago, nearly all the principal industries showed an improvement. There was, however, a considerable decline at blast-furnaces and in the lace and jute trades.

In the 394 trade unions, with a net membership of 758,666, making returns, 22,895, or 3.0 per cent., were returned as unemployed at the end of June, 1911, compared with 2.5 per cent. at the end of May, 1911, and 3.7 per cent. at the end of June, 1910.

Returns from firms employing 450,221 workpeople in the week ended June 17, 1911, showed a decrease of 2.3 per cent. in the amount of wages paid compared with a month ago, and an increase of 2.8 per cent. compared with a year ago.

With one exception all the changes in wages reported as taking effect in June were increases, and affected 27,400 workpeople, of whom 21,600 were employed in engineering works on the North-East Coast. The only decrease affected 190,000 coal-miners in South Wales and Monmouthshire, but its effect was more than sufficient to counterbalance that of all the increases reported, with the result that the net effect of the changes during the month was a decrease of 840*l.* per week.

The most important disputes in progress during the month were those involving about 65,000* seamen, firemen, dock labourers, and other transport workers at various ports in the United Kingdom, 19,000 woolcombers, &c., at Bradford, 12,000 coal-miners in the Rhondda Valley, 1700 coal-miners at South Shields, 1400 coal-miners at Wigan, 800 builders' labourers at Nottingham, 400 carpenters and joiners at Burnley, and 500 railway surfacemen in the Glasgow district. The new disputes beginning in June, 1911, numbered 36, and the total number of workpeople involved in all disputes in progress during the month was 116,334, or 79,466 more than in the previous month, and 99,868 more than in June, 1910. The time lost during the month by these workpeople amounted to 1,214,100 working days, or 690,300 more than in May, 1911, and 1,057,900 more than in June, 1910.

Cases reported under the Conciliation Act affected seamen, firemen, dock labourers, and other transport workers at various ports, steel-workers in Scotland, steel-melters at West Hartlepool, building trades' operatives at Southampton, shoddy and mungo workers at Ossett, and matting weavers in East London. Settlements in the form of agreements or awards were made in certain cases of the seamen, &c., the steel-melters at West Hartlepool, and the shoddy and mungo workers at Ossett.

* This is the estimated number affected up to the end of June.

* In addition to the ordinary short time which occurs in all trades, it should be noted that in the mining and textile industries a contraction in the demand for labour is more generally met by a reduction in the time worked per week by a large number of workpeople than by the discharge of a smaller number.

On Wednesday last a development in connection with the seamen's strike at Cardiff took place, for it was resolved by 5000 dockers that they would support the seamen's demand that their union should be recognised. It is the object of the malcontents to block every ship in Cardiff. The Shipping Federation has again been challenged by Mr. Havelock Wilson, who threatened that he will call 50,000 men out in the Port of London next Monday if a conference is not granted by the Federation. There is much unrest, and riots have taken place.

The North-Eastern Railway men held a demonstration on Sunday last at the Town Moor, Newcastle-on-Tyne, between 4000 and 5000 men taking part in a procession. The demonstration was organised as a protest against the employment of non-union men in the ranks of labour, and was arranged by representatives of the Amalgamated Society of Railway Servants, and by members of the General Railway Workers' Union. Representatives of the Northumberland Miners' Union were also present. Protests were raised against the non-unionists reaping the benefits of trade-unionism, and yet remaining outside organised labour. The General Railway Workers' Union passed a resolution dealing with the dispute over the programme which has been under consideration by the representatives of the railway company at York. This resolution was as follows:—"We desire to inform the general secretary of the railway company that, unless the programme is fully discussed by July 19, voting papers will be issued to all members of the union to ascertain their present position with regard to it, and to take such steps as may be necessary."

The railway workers at Hull also held a meeting on Sunday last, and carried the following resolution:—"That this meeting of railway workers is of the opinion that the time has now arrived when every man must be a member of his own union, and pledges itself that, when the date is fixed, no one will work after that date with non-union men."

Negotiations between masters and men in the engineering trades have resulted in an increase of wages of 1s. per week at Blackburn, with the promise of a further 1s. in March, 1912, should the textile industry be maintained at its present satisfactory state. Excluding the shipyards at Belfast, the employers have now agreed to an immediate increase of 1s., and another 1s. in January next. The men have confirmed the agreement in each case. At Leeds and Aberdeen disputes are still outstanding. The agreements for the regulation of wages in the engineering trade are binding for a comparatively long time.

It was officially announced on Monday last that the vote taken in the ballot of Northumberland miners for and against a strike to abolish the three-shift system showed that a two-thirds majority was in favour of a strike. It is stated that the Miners' Federation of Great Britain will consider the Northumbrian miners' request for a national stoppage in order to enforce their wish. The outlook appears very gloomy. It will be remembered that at the beginning of last year, when the Eight Hours Act came into force, the employers at several of the collieries found it necessary to institute the three-shift system, and there was great opposition to it, chiefly on account of the effect it had on the domestic arrangements of the colliers and on their social life. The men, however, agreed to give the system a trial. There has since been much negotiation with the coal-owners, but with no result. The attempt to secure a minimum wage of 30 per cent. above the standard has failed, and the Northumberland Conciliation Board has consequently terminated. The employers state that increasing working costs make it impossible to accede to the men's request for an increase in this respect.

According to the semi-monthly report of the American Association of Commerce and Trade, the German workmen's insurance system, which has been in operation since 1884, has grown into a very large system of co-operative relief. It is, however, very complex and full of abstracts of law. The system is threefold, embracing: (1) Invalidity insurance, (2) sickness insurance, and (3) accident insurance. The first of these provides an annuity for those who are unable to make a living, if this incapacity is caused by a bodily or mental defect, chronic sickness, or natural decay of the physical powers and old age. It covers all persons over sixteen years of age who are working for salaries or wages in the following occupations:—Workmen, apprentices, domestic servants, sailors, and employees of the textile and tobacco home industry, commercial and technical employees and teachers, provided their yearly income does not exceed 50*l.* Employers and employees contribute to it in equal parts, the Government adding a fixed sum to each allowance paid, and the contributions are paid weekly on a fixed scale, the amount depending on the salary of the insured person. These weekly contributions vary from 1½d. for a yearly income of about 17*l.* to 4½d. for a yearly income of about 55*l.*, and the contributions are made by stamps, which are affixed to a card, the stamps being provided by the employer, who is responsible for the contributions being paid regularly, and who is entitled to deduct half of the value of the stamps from the salary or wages of the insured. Old-age pensions are payable on the completion of the seventieth year of the insured, provided he has made a certain number of payments.

Sickness insurance includes workmen employed for salaries and wages in mines, quarries, factories, smelting works, shipbuilding yards, transport by land and inland waterways, building handicrafts, commercial and professional offices, and the Post Office, Army, and Navy departments. The mercantile marine, agriculture, and forestry, however, are not included. The payments are made by the employers and employees in the proportion of one-third to two-thirds respectively, and vary from 2 to 4 per cent. of the salary of the insured. The insured are entitled to medical attendance, drugs, and treatment, whether unable for work or not; in the former case, sick-pay commences from the third day of illness. In the case of women pay continues for six weeks after confinement. All insured get funeral expenses. Sick-pay is not less than half the average rate of wages, but does not exceed 1 dol. a day, and is payable for twenty-six weeks, which, under special conditions, may be extended to one year.

Accident insurance applies to the same classes as sickness insurance, but includes also agriculture and forestry, divided into the following classes:—Industry and transportation, agriculture and forestry, building and construction, and the mercantile marine. Persons employed in shops and offices, as well as domestic servants, are not included. The employers provide the whole of the funds, the amount being based on salaries and wages paid. Compensation does not begin until after the expiration of a period of thirteen weeks from the time of the accident, during which time compensation for sickness insurance is paid. Accident payments include medical treatment, drugs, and appliances—an allowance, in case of complete incapacity to work, at the rate of two-thirds of the wages previously earned, and funeral expenses according to a fixed scale. The latest German Government reports give the following figures, which show the number of insured persons with the amount of expenditure and receipts in 1908:—

THE ROYAL AGRICULTURAL SOCIETY'S SHOW: ERRATUM.—A misprint has crept into our article on page 5 *ante*, column 2, in our description of Messrs. Davy, Paxman, and Co.'s engine. The maximum power this engine can develop is 90 brake horse-power, and not 30, as we stated.

PROGRESS IN NAVAL ARTILLERY.*

By Sir ANDREW NOBLE, Bart., K.C.B., LL.D., F.R.S., Hon. Vice-President.

WHEN I was asked by the Council to write a paper on the progress which artillery has made during my lifetime, I must confess to having been a little unwilling, as I thought I had already said quite enough on the subject to tire my naval and military friends; and, as regards the subject, I remembered a conversation I once had with a very eminent scientific friend, who, when I was expressing my regret that we could not expect to live to see the solution of the difficult question we were discussing, replied that I ought to be content, because the progress of the world during my lifetime exceeded in importance all that had been done in the ages which had preceded us. His remark was, I think, perfectly true, and it certainly applies to artillery, both as regards the guns and the propellants and explosives employed. When I joined Her Majesty's Service, now about 64 years ago, no appreciable advance had been made in artillery during 500 years, either in gunpowder or its mode of manufacture, and but little, except in size, and that not very great, in the guns themselves.

To give you an idea of how slow was the increase of power in guns from the time of the Armada, I may mention that the armament of Nelson's flagship, the Victory, which consisted of 102 guns, included sixty 42, 32, and 24-pounders; forty 12-pounders, and two 68-pounder carronades; the weight of the heaviest gun being 75 cwt. The armament of the Duke of Wellington, commissioned just before the Crimean War, consisted of 131 guns, there being seventy-two 8-in. and 32-pounders on the lower and middle decks, thirty-eight 32-pounders on the main deck, and twenty short 32-pounders and one 68-pounder pivot gun on the upper deck. Taking the most powerful gun, the 68-pounder, the maximum velocity realised with the Service charge was a little under 1600 foot-seconds, and the maximum energy 1170 foot tons. I have alluded to the small advance made in the construction of guns during 500 years. The guns of Her Majesty's ship the Duke of Wellington were merely blocks of cast iron, and the machining to which they were subjected consisted only in the formation of the bore and the drilling of the vent. The carriages on which they were mounted were equally rude; they were made entirely of wood, generally in the later days of teak and mahogany; they were carried on wooden trucks, the rear trucks being frequently replaced by a wooden chock. The recoil was controlled by the friction of large wooden axles and big wedges under the trucks, and was finally brought up by the breechings by which the carriage was attached to the vessel's side. The elevation was given by quoins, and hand-spikes were used either for training or elevating. For running-out, blocks and tackle were generally employed. To work with any degree of smartness these rude weapons, a very strong gun's crew was necessary; indeed, the gun was practically surrounded by its crew, which numbered fourteen or fifteen men. The much more powerful modern 6 in. gun is served by three or four men.

In the year 1858, the first great step in artillery progress was made. In that year the Committee on Rifled Cannon, of which I was secretary, was appointed, and experiments with the various guns submitted to them were made, but the superiority in accuracy of the gun submitted by the late Lord Armstrong was so conspicuous, and the details, as regards projectiles, fuses, &c., were so superior, that the Committee unanimously recommended the adoption of his system. With regard to range, accuracy, and penetrative power, the superiority of the rifled guns was so great that it was evident to nearly all naval and artillery officers that the days of smooth-bored guns were numbered. But the point which occasioned most surprise was the extraordinary increase in accuracy. The Rifled Cannon Committee fired forty rounds from the smooth-bored field gun of the Service, and a similar number from the Armstrong rifled field gun. I used the method of least squares to determine the relative accuracy of the two guns, and found that, with the rifled gun, at a range of a little more than 1000 yards, half the shot fell in a rectangle of about 23 yards long by 1 yard wide, while with the smooth-bored field gun the similar rectangle was about 145 yards long by 10 yards broad. You will however, more readily appreciate the difference, if I show a diagram giving the comparative areas of the rectangles to which I have referred. (Fig. 1.)

The great success which had attended the application of rifling to the smaller nature of guns led to the immediate construction of rifled guns. But the additional complications of breech-loaders were looked on with dislike by the older officers, and this feeling lasted a considerable time, leading to the abandonment for some years of the construction of breech-loading guns. It led also to England being, for a considerable time, behind the principal Continental nations, owing to her refusal to adopt improvements until (which will never happen) finality was reached. It is curious to look back fifty years and compare what were then considered impossibilities with the realities which are in existence at the present time. To illustrate the distrust and doubt with which novelties were regarded, I may mention that I was secretary to a committee of naval and artillery officers on plates and guns, and at their meetings there was discussed the weight and calibre of a gun intended to be the heavy gun for both land and sea service. The artillery officers preferred a gun weighing 7 tons, but the naval officers were doubtful whether so heavy a gun could be carried on board ship. The point was finally compromised by making the gun 6½ tons—I need not point out to you that our ships are now carrying guns more than ten times as heavy as the weight then considered impossible. Twenty of these guns, known as the Somerset gun, were constructed, but the advisability of adopting rifling was then considered so doubtful by the authorities that it was ordered that the bore should be large enough to carry a smooth-bore shell of nearly the same weight as the rifled shell. The guns, when completed, were practically useless, and few of them were ever put on board ship. In the days to which I refer, the older officers could hardly be got to look with patience on any appliance to which they were not accustomed, and which could not be made or repaired on board ship, but there is now a very great change in this respect. Too much praise cannot be given to the naval officers of the present day for the ability and zeal they have shown in mastering, and their skill in using, the various and, in some cases, the complicated machines committed to their charge.

I need hardly point out that the battle between guns and armour rendered it most important that the velocities of rifled guns, which at the outset were very low, should be increased. The first step in this direction was made by the Committee on Explosives, who, by their experiments, showed that with improved forms of powder the velocities, which originally had generally run between 1200 ft. and 1350 ft. a second, were in the same guns raised to 1600 ft. a second, the increase in velocity being at the same time accompanied by a very considerable reduction of maximum chamber pressure. But the most important step was made by my firm, who, acting on certain experiments made at Elswick, and which were reported in a paper communicated to the Royal Society, made, in 1877, 6-in. and 8-in. breech and muzzle-loading guns, with which, while the maximum pressure remained the same, the velocities of the projectiles were, at a single bound, raised from 1600 foot-seconds to 2100 foot-seconds, thereby increasing the energies by nearly 75 per cent., and necessitating a reconstruction of guns and their mountings. At the same time, from the increase in the length of the guns which the high energies then introduced demanded, a return to breech-loading, from the retrograde change to muzzle-loading, which some years before had been adopted, was also necessitated. I need hardly say that since that date the weight and power of heavy guns have been enormously increased. We have now 12-in. guns of a weight of 68 tons and with a velocity of over 3000 foot-seconds and an energy of 58,600 foot-tons, that is, an energy forty-five times greater than that of the most powerful gun when I entered Her Majesty's service; while 14-in. guns are being made which, with a very moderate velocity, will be capable of piercing 15 in. of K.C. armour at ranges between 7000 and 8000 yards.

Turning now to quick-firing guns, I shall consider the guns in connection with their mountings, as these last, when rapidity of fire is considered, are nearly as important as the guns. Early in 1887 the gun and mounting I now show you (Fig. 2) were submitted for trial on board H.M.S. Handy. The gun was the first mounted on the Elswick cradle, having the recoil-press and spring-box beneath the cradle. The weight of the gun and mounting was taken on the balls under the pivot, the mounting and shield being carefully balanced. The

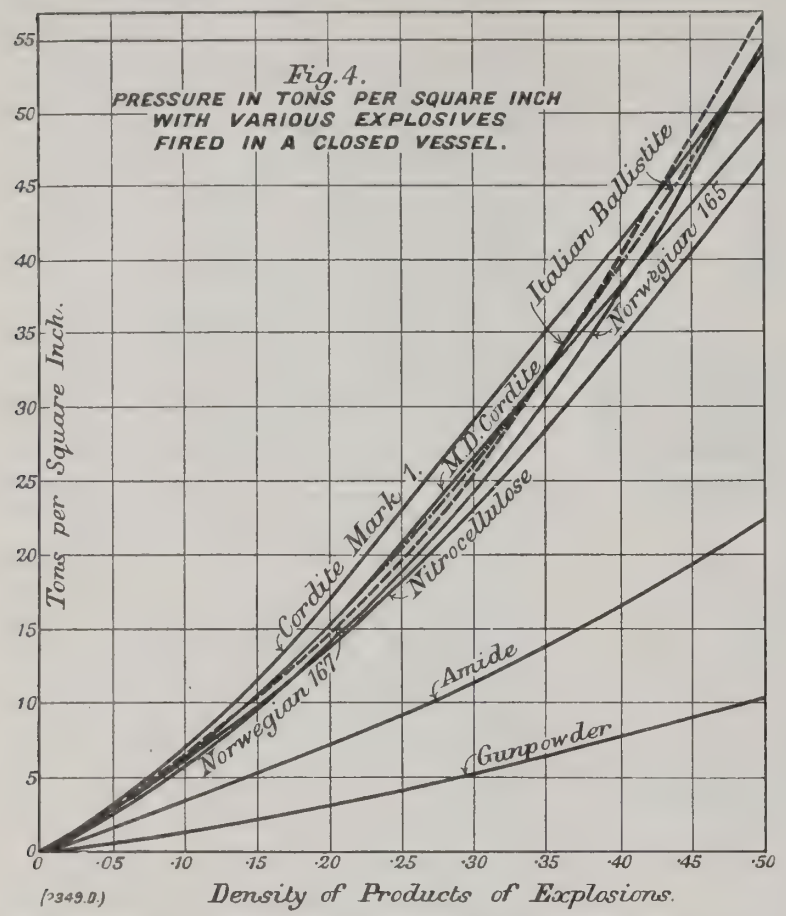
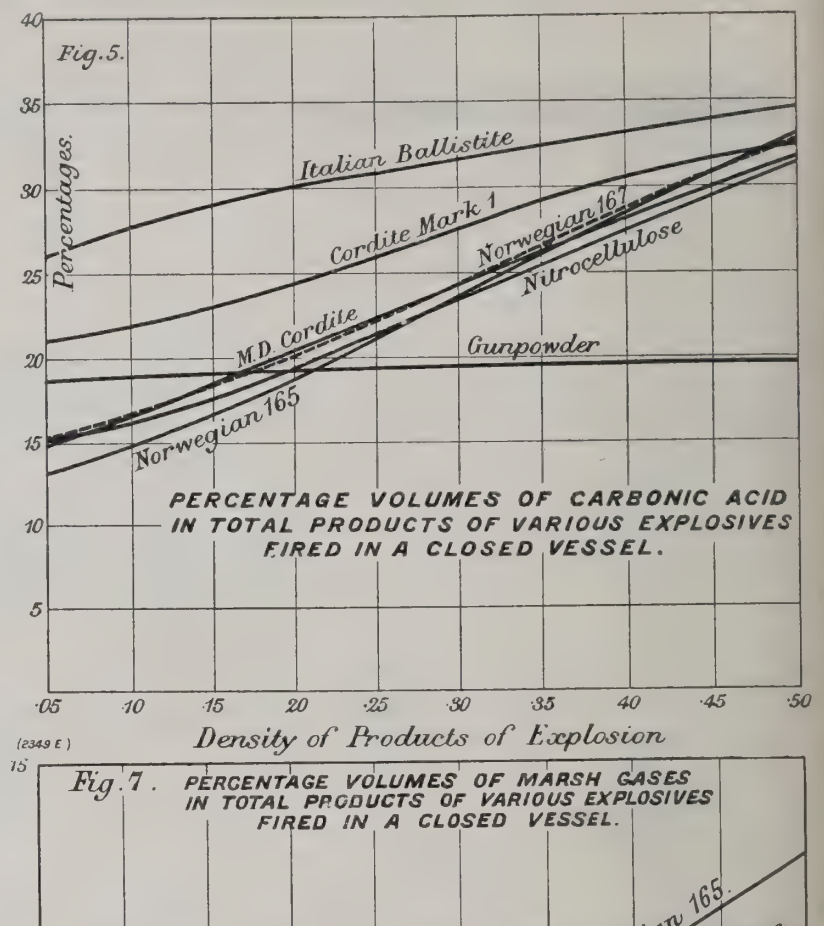
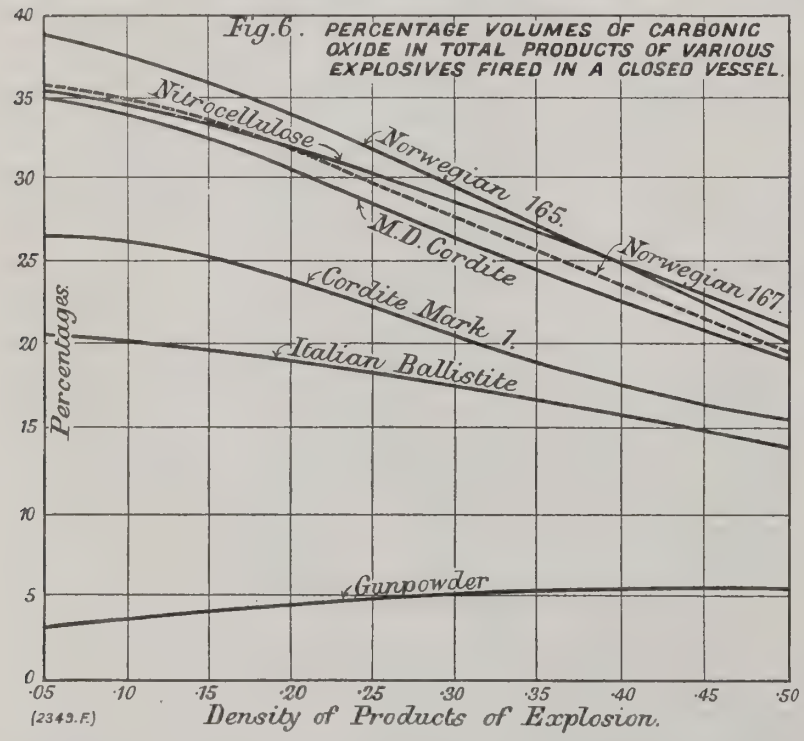
* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 5, 1911.

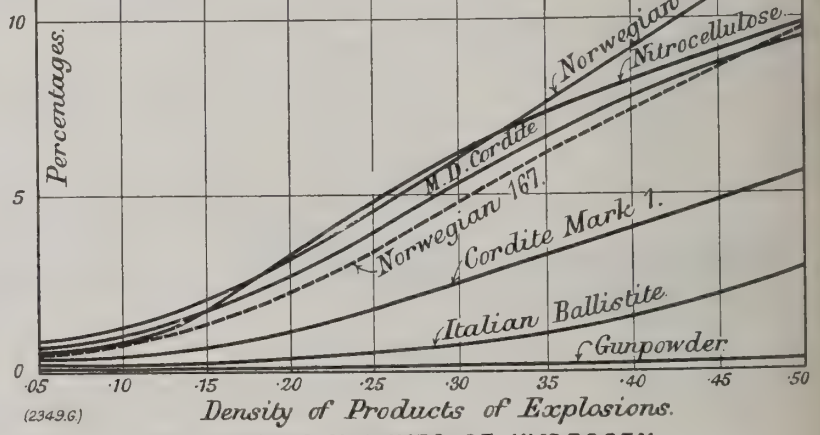
whole weight of the gun and mounting was under 5 tons, and the gun could be trained easily by the shoulder. The sights were on the cradle and did not recoil with the gun. A single man could with ease train, work the elevating gear, lay and fire by means of an electric pistol. With this gun and mounting a very accuracy, of the modern gun are even more remarkable.

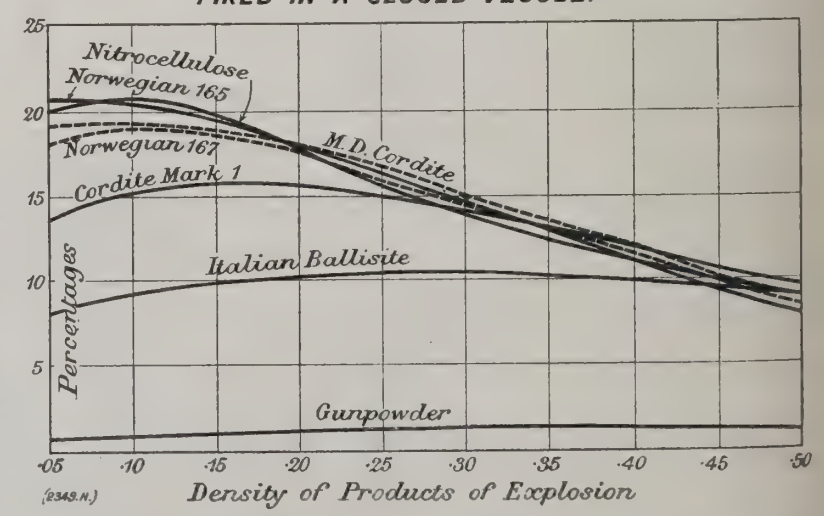
In what I have hitherto said I have referred chiefly to guns and the energies they were capable of developing; but, if the increase in the dimensions and power of the guns is remarkable, the increased power of the pro- 10,000 atmospheres. But the experiments which, for a long time, were taken by many to be tolerably reliable, were those of Count Rumford, who, in 1797, communicated to the Royal Society the results of two series of experiments, from one of which he deduced that the maximum pressure was, at a density of unity, about 190











great advance in rapidity of fire was obtained. At the trial above mentioned ten rounds were fired in 47½ seconds, and later as many as fifteen rounds per minute were obtained. I may mention an interesting incident connected with this trial. The gunboat Mastiff was sent the same day, and was ordered to fire ten rounds from the Service 5-in. breech-loading gun as rapidly as possible. The time taken for the ten rounds was 6 min. 16 sec., so that the quick-firing gun fired its ten rounds before the then Service gun fired its second shot.

On the diagram I now show you (Fig. 3) are placed side by side sections of the 6.3-in. smooth-bored gun of 1850, and of the 6-in. 100-pounder of the present day. The diagrams show the pressures and velocities of the two guns. The velocity and energy given by the 32-pounder smooth-bored gun are about 1600 ft. per second and 570 foot-tons respectively. The corresponding figures for the 6-in. are about 3000 ft. per second and 6240 foot-tons energy, but the rapidity of fire, the range and pellants is quite as much so. During more than fifty years I have made very many hundreds of experiments, and completely examined eighteen different propellants, determining, for most of them, the changes in transformation which take place when the propellant is fired at different densities. And first, as regards gun-powder and the pressure produced by its explosion, I do not know any physical fact as to which, for many years, so wide a difference of opinion prevailed. Robins, the Father of Gunnery, put the pressure developed at a density of unity at 1000 atmospheres, or 6.6 tons per sq. in., while Hutton put it at 2000 atmospheres, and Daniel Bernoulli, who was nearest the truth, made it tons per sq. in. This, however, he considered to be much below the truth, and he finally believed the pressure per square inch to be 662 tons. This latter pressure never seems to have been accepted, but in my own time Piobert accepted as tolerably correct Rumford's first series, and fixed the tension of gunpowder at the density of unity at

150 tons on the square inch, while Cavalli, in 1867, made the tension 158 tons per sq. in. On the other hand, text-books used at the Royal Military Academy, Woolwich, so late as 1870, placed the tension as low as 2200 atmospheres, or 14 tons on the square inch.

Referring to the high estimates I have mentioned, it is curious that as no such pressures were obtained in guns, this being attributed to slow combustion, no attention was paid by the eminent men I have mentioned to Robins's remark that the powder he employed must have all been exploded before the projectile was much removed from its seat, as, were it not so, a much greater energy would be realised when the weight of the shot was doubled, trebled, &c., but he had found that there was no very material increase. I myself, nearly a century and a-half later, repeated Robins's experiments with means at my disposal far greater and more accurate than anything he could have employed, and these experiments entirely corrobated the accuracy of his views.

The long series of experiments I made, and described in a paper, published by the Royal Society, by myself and my friend the late Sir F. Abel, set at rest the question of the pressures and temperature of fired gunpowder, as I was able with several varieties of powder to obtain the pressures and to examine the solid and gaseous products of combustion at all densities from 0.05 up to that of unity, the products being entirely confined after explosions, and the pressure at a density of unity was found to be about 42 tons per sq. in. The decomposition of these powders was affected by the pressure under which they were exploded, but only very slightly, and much less than was the case with the more modern explosives of which I shall have presently to speak.

I have alluded to the long period during which gunpowder remained unchanged, and it was only shortly before it was its fate to be replaced by modern explosives that any attempt was made to improve it The first step in this direction was made by Major Rodman, U.S.A., who not only appreciated the importance of the size and density of the grains in diminishing excessive pressure, but invented a most ingenious instrument for determining the pressure of the exploded gases. Before the adoption of the pebble, P 2, and prismatic powders, which were due to the labours of the first Explosion Committee, the chamber pressures indicated were very high, and occasionally ran exceptionally high, but these exceptional pressures did not exist at the same instant throughout the chamber, but were due to waves passing backwards and forwards between the end of the chamber and the base of the projectile. Some of these wave pressures have been observed 50 per cent. higher than the pressures due to powder exploded in a close vessel at the density of unity, that is approximately in its own space.

But I must turn to modern explosives. Of these I have examined pretty completely eight varieties (nine if I include Amide powder, the energy of which is about 60 per cent. higher than that of the old powder. If we compare the potential energies of the old powders of the Service I examined, these varied from 200,438 units in the case of pebble powder to 194,094 units with that known as F.G. The comparative energies of other old powders are, as you will see from the tables on page 93, some a little higher, others somewhat lower, but, with the exception of the Amide powder, there is no very great difference in the energy developed, and but little in the decomposition which takes place when exploded at different densities.

The erosion belt used for half-charges of Cordite Mark 1 was burned through on one side at the eleventh round, and could not be used again.

* These figures are the estimated continuation of Cordite Mark 1.

The case is very different with the modern propellants. With gunpowder the products of combustion, when cool, are about 43 per cent. by weight gaseous and 57 per cent. solid, and they include seven gases, the same number of salts, and two elements. With modern propellants the products are only six—five gases, and water, the amount of which in the different explosives varies from about 12 to 20 per cent. of the total weight. With gunpowder, as I have said, there is, with increased density of charge, but little difference in the decomposition, and the quantity and nature of the products differ but little. The case is, as I shall shortly show you, widely different with high explosives.

Table I. gives the volumes of gas, units of heat and energy of the older explosives. Table II. also gives the same details of the modern explosives I have examined, and you will note that the energies vary from nearly 5½ times to 4¼ times as great as that of gunpowder, cordite developing the highest energy. With gunpowder, as I have said, there is, with increased density of charge, but little difference in decomposition, the percentage and nature of the products of explosion differing but little. With high explosives the case is widely different; but, before going into details, it will be as well to give you an idea of the differences of pressure between the old powders and the modern propellants at the same density. Fig. 4 is a diagram which exhibits up to the density of 0.5 the pressures of gunpowder and of several modern propellants. You will observe that at the density of 0.5 the pressures of the modern propellants are about five times as great as that of gunpowder; but I need not say we do not allow these pressures to be developed in guns, the maximum in that case being about 20 tons on the square inch.

The pressure of gunpowder at the density of unity, as I have said, is about 42 tons per square inch. I have made more than one effort to obtain the pressure of cordite at the same density, but have not been perfectly successful, as my gauges were always crushed upon the piston by the high pressure. I know, however, the pressure to be considerably above 100 tons, and believe the true pressure at the density of unity to lie somewhere between 108 and 115 tons on the square inch. Unlike gunpowder, the decomposition of modern explosives differs greatly with the pressure under which they are exploded. The quantities of the nitrogen and water formed are not much affected, but with increased density considerably larger percentages of carbonic acid and marsh gas are formed. As an illustration, in the case of Norwegian Ballistite, in passing from a density of 0.05 to that of 0.5, the carbonic acid is increased from 13.40 per cent. to 33.4 per cent., the carbonic oxide being decreased from 38.5 per cent. to 19.5 per cent. Similarly, with the same explosive at the same densities, the marsh gas is increased from 0.4 per cent. to 12.55 per cent., the hydrogen being decreased from 20.6 per cent. to 7.4 per cent.

The rapid increase in the amount of carbonic acid and marsh gas at the higher densities, accounts at once both for the decrement in the volume of the total gases formed by the explosion, and for the very much greater heat developed at the higher density. Thus, in passing from density 0.05 to density 0.5, the volume of the gases per gramme falls from 959 to 780 volumes, while the temperature of explosion is increased by about 1500 deg. Cent. Although there are great variations in the percentages of the gases to which I have referred, the same general law as to increment or decrement of volume with increase of density is followed in all the explosives with which I have experimented.

Thus, in the diagram giving the percentage volumes of carbonic anhydride, Fig. 5, you will note that, with increasing density, the percentage of CO_2 steadily increases, and is in marked contrast to gunpowder, where the CO_2 can hardly be said to alter at all. I may point out also that with increase of density the differences in the volume of carbonic oxide in all the propellants examined steadily decrease as the densities increase, and are not great at the density of 0.5. As a matter of course, the volumes of carbonic oxide decrease as those of carbonic anhydride increase, and I exhibit a diagram (Fig. 6) showing the percentages of this gas up to the same density. As regards gunpowder, the increase in density causes but little change in the percentage of carbonic oxide, even up to the density of unity, and, unlike the modern explosives, the changes appear to be in a great measure independent of the density.

Turning now to marsh gas and hydrogen, the variations in their percentage at different densities are very striking. These variations also are more easily appreciated by means of diagrams, and, as before, I give you curves showing the volumes of each gas at the different densities (Fig. 7). Commencing with marsh gas, you will see that at the density of 0.05 the percentage is, with all the propellants, exceedingly small, the largest being under half a per cent. The increments, you will note, are very variable with the different propellants; the Italian Ballistite being only at a density of 0.5 about 2½ per cent., while one of the Norwegian Ballistites reaches over 12½ per cent. With the old gunpowder, the percentage of marsh gas is, as you see, almost infinitesimal, and is nearly constant. On the other hand, the differences in the percentage of hydrogen at the low densities (Fig. 8) are very large, varying from about 8 per cent. to nearly 21 per cent., while at the density of 0.5 the differences nearly disappear, being considerably under 2 per cent. You will observe also that with gunpowder the percentage of hydrogen is, as in the case of marsh gas, exceedingly small, being very uniform, and only about 1 per cent.

The only other point to which I shall draw your attention is the question of erosion. As erosion increases at so rapid a rate with increase of calibre, it becomes of importance in the larger guns to have the length as great as possible, as by so doing the amount of the charge is very greatly decreased. I may add that I think erroneous opinions as to the decrease in erosion due to the decrease in charge have been entertained, and I conclude my paper by giving you Table III., showing the erosions due to full, half, and quarter-charges of different propellants.

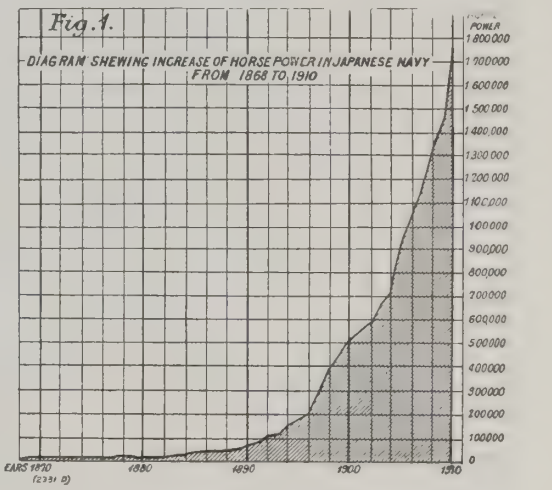
PROGRESS OF NAVAL ENGINEERING IN JAPAN.*

By Engineer Rear-Admiral TERUGORO FUJII, I.J.N., Member.

THE increase of horse-power in the Japanese Navy has become somewhat remarkable since 1896, as will be seen from Fig. 1. The total horse-power and number of ships built or building will be gathered from Table I., and it will be seen that nearly 28 per cent. of the total indicated horse-power of our warship machinery comes from Great Britain.

In the following remarks I intend to give a brief account of the evolution of ship machinery, with reference to Table II., page 96, and the drawings given.

Boilers.—The gunboat Chiyoda Gata, the first steam-driven ship built in Japan (1863), was equipped with three low-pressure cylindrical boilers of the locomotive type. Subsequently, either locomotive or return-tube boilers were adopted for every ship launched before 1899. In 1900 the Normand type was installed in the despatch boat Chihaya; and next year the high-type cylindrical boilers of the Itsukushima and Matsushima were replaced by Belleville boilers; and those of the Hashidate by Miyabara boilers, invented by our Admiral Miyabara, this being the first time that this boiler was used on a warship. Then in 1902 the locomotive and low-type cylindrical boilers on the Chiyoda, as well as the Yayeyama, were replaced by boilers of Belleville and Niclausse types respectively. These afforded us opportunity for very important investigations with regard to water-tube boilers; and on a training cruise for our naval cadets to Australia and back, the Miyabara boiler fitted in the Hashidate proved very satis-



factory. This fact was also confirmed by the experience of rough usage during the late war. Since that time, the Japanese authorities have decided to adopt the same for nearly all ships of new construction in Japan; and, in fact, the Tsukuba, Ibuki, and Satsuma have already given good results on their trials with this type of boiler on board. Also the first-class battleships Kawachi and Settsu, now under construction, are to be equipped with Miyabara boilers of double-ended type. Figs. 2 and 3, page 96, show the boiler for the cruiser Tsukuba. As may be seen from the drawings, the construction of the Miyabara boiler is comparatively simple, having horizontal water and steam drums, with slightly-curved tubes connecting them. From the nature of its construction, this type is very elastic and contains a comparatively large quantity of water; moreover, the water circulation being always efficient, it gives no trouble from leakage.

TABLE I.

Class.	Where Built.	Number of Ships.	Total H.-P.
Warships	Home	45	573,617
	Great Britain	47	376,540
	Elsewhere	32	254,652
	Total	124	1,204,809
Destroyers	Home	45	306,000
	Great Britain	16	95,050
	Elsewhere	5	23,000
	Total	66	424,050
Torpedo-boats	Home	58	77,029
	Great Britain	10	19,217
	Elsewhere	25	39,804
	Total	93	136,050
Submarines	Home	6	3,400
	Great Britain	2	1,200
	Elsewhere	5	1,500
	Total	13	6,100
	Grand total	296	1,771,009

On the other hand, in 1903, another type was tried for the third-class cruiser Otowa, and, its results being very satisfactory, this type was used for 28 destroyers constructed in the year 1904. Figs. 4 and 5, page 96, show the boiler of the destroyer Ayanami. We named this boiler "Navy Type," as it is an express type specially used

* Paper read at the Jubilee Meeting of the Institution of Naval Architects, July 6, 1911.

* Replaced with eight Niclausse boilers in 1904.

† Replaced with eight Miyabara boilers in 1901.

for our navy. This type is very similar to that of the Yarrow boiler, but the tube has a certain curvature instead of being straight, which gives sufficient elasticity for expansion and contraction of all parts. This curvature also gives much more space for cleaning the boiler, and effective heating is insured by the insertion of proper baffle-plates. Table III., page 97, shows the result of evaporative tests of Miyabara and "Navy Type" boilers, from which may be seen the gain in boiler power due to utilisation of oil-fuel.

Reciprocating Engines.—The Chiyodo Gata was installed with a horizontal-geared direct-acting engine of

* The horse-power mentioned here is decided by the number of revolutions counted before the order to go astern.

60 horse-power, to drive a single-screw propeller, which was really the first marine engine ever built by Japanese hands.

In 1875 a return connecting-rod compound engine of 443 horse-power was installed in the wooden gunboat Seiki; while in the Jingei, an imperial yacht, a diagonal direct-acting engine of 1490 horse-power was tried to drive her paddle-wheels. Then for a decade or so, either horizontal direct-acting or return connecting-rod types were used. In 1890 a vertical triple-expansion engine, developing 1200 horse-power, was installed in the Oshima, and a vertical triple-expansion engine of 8500 horse-power, in the protected cruiser Suma. As a consequence of this increase in horse power in 1902, vertical four-cylinder triple-expansion engines of 9500 horse-power were installed in the cruiser Niitaka. In 1906 two sets of vertical four-cylinder triple-expansion engines of 22,000 designed

horse-power were built for the first-class cruisers Tsukuba and Ikoma; also the same type of engine, developing 18,500 horse-power, was installed in the first-class battleship Satsuma. These engines are all fitted with forced lubrication system, which has given very satisfactory results.

Steam-Turbine.—The prominent success of the Parsons turbine having undoubtedly encouraged marine engineers in all countries to try the turbine system for naval work, our authorities decided to try one set of Parsons' turbines of 8000 brake horse-power for the despatch-boat Mogami in 1907. Later in the same year we adopted two sets of seven-stage Curtis turbines for the Aki and the Ibuki, as their size, weight, revolution, steam consumption, and cost, made it desirable to replace the reciprocating engines with which they were originally designed.

An improvement has been made for all Curtis turbines of new design, on a part of the drum and second-stage stern-wheel, to counterbalance the propeller thrust by means of steam-thrust, so that the thrust-shaft and collar may be made comparatively short.

The result of the steam consumption trial for the Ibuki is shown in Table IV., page 97. With regard to her manœuvring, we found it fairly good as compared with that of ships fitted with reciprocating engines. Table V. gives the results of trials.

Cost of Propelling Machinery.—The cost of propelling machinery for the gunboats Atago and Takao varies from 50 yen to 55 yen* per horse-power, and that of twenty-eight destroyers, built in 1902, was found to be 35 yen. In the case of the armoured cruiser Tsukuba and the Ibuku, the cost was 98 yen and 95 yen respectively, the latter being equipped with Curtis turbines, while that of the first-class battleship Satsuma was nearly 115 yen per horse-power. Generally speaking, the cost of propelling machinery in Japan seems slightly less than it is in Europe and America. This is probably due to the lower wages of workmen, notwithstanding the higher price of imported materials. Though the wages in Japan are still much lower than those of Europe or America, they are constantly getting higher, and during the last fifteen years the pay of workmen has increased from 32 sen (8d.) to 66 sen (1s. 4d.) per day of about 10 hours' work.

Personnel.—The number of officers and men belonging to the Engineering Corps of our navy at the end of 1910 was as shown in Table VI. And the total number of workmen engaged in marine engineering in the Imperial Dockyards at the end of the same year was summarised as being 9200. Of these, 3300 men were employed at Yokosuka, 2300 men at Kure, 1900 men at Sasebo, and 1300 men at the Maidzuru Dockyard, and the remainder at various other places.

Effect of War on Machinery.—It is gratifying to mention that the machinery of our squadrons had not shown any defects such as to affect the action of our fleet during the whole course of the recent war, and it may be worth mentioning that some of the warships were continuously under steam for over 2000 hours. The only noticeable trouble which our engineers experienced was the leakage of both main and auxiliary condenser-tubes. Also, I may add, that the spare parts of auxiliary machinery were found indispensable, they having been used very often.

Fig. 6.

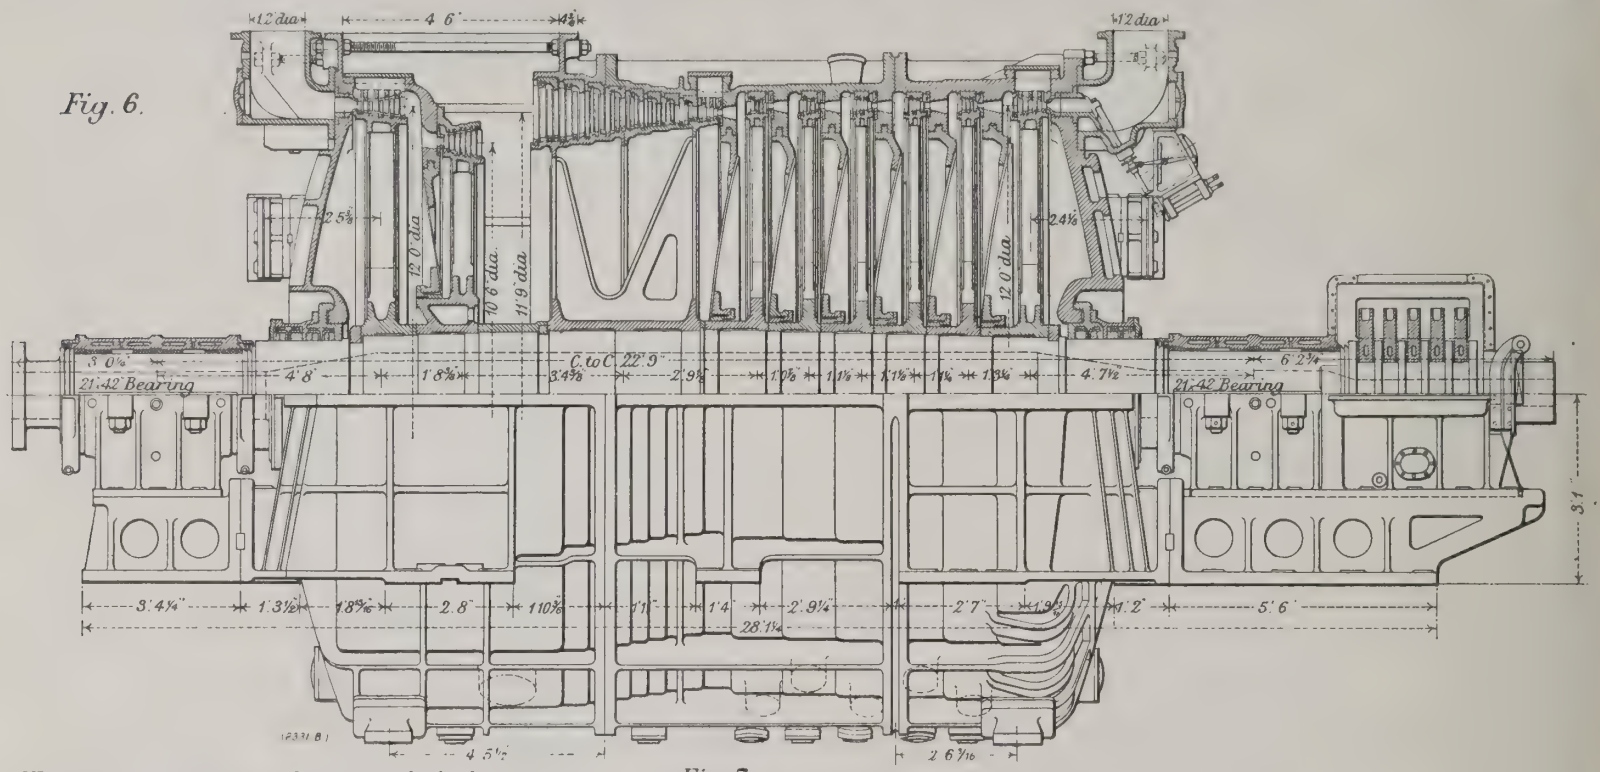

Fig. 7.

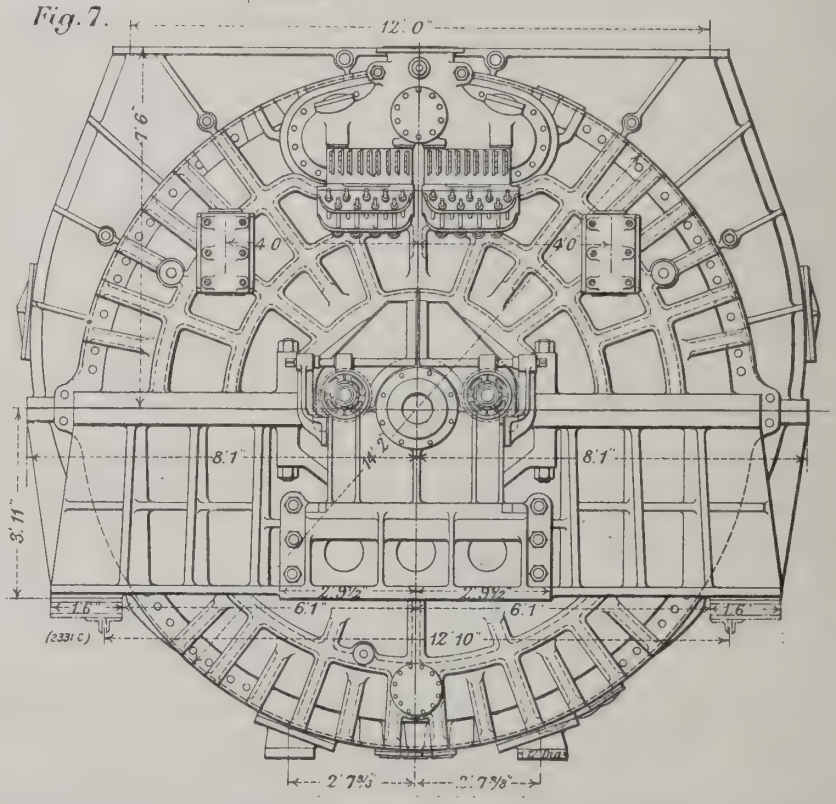

We, moreover, propose to adopt 25,000 brake horse-power Curtis turbines for two of the first-class battleships, Kawachi and Settsu, and 22,500 brake horse-power Curtis turbine sets for two out of three scout cruisers. For the remaining scout one set of Parsons turbines of the same power will be used, and two sets of the Parsons type of 20,500 horse-power for two destroyers. Also the latest improved Parsons turbines of 64,000 brake horse-power are to be installed for three first-class armoured cruisers, one to be built in England and the remainder at home; and a Curtis turbine installation of same power is to be equipped in another first-class armoured cruiser which will be built at home.

TABLE VI.—*The Engineering Corps of the Japanese Navy.*

Those in Charge of Construction and Repairs.				All other in Charge of Ships, &c., except the Preceding.		Total.

Total	14,592

Figs. 6 and 7, above, show the fifteen-stage Curtis turbine for the battleships Kawachi and Settsu. The diameter of the turbine is 12 ft. at its pitch circle for these battleships and cruiser, and it is designed for 27,000 brake horse-power at 270 revolutions for the seven-stage, and 25,000 brake horse-power at 245 revolutions per minute for the fifteen-stage turbine. The latter consists of six ahead wheels and one ahead drum carrying nine stages, and two reverse wheels.

Regarding the machinery of destroyers and torpedo-boats, from which we naturally expected some trouble, they proved perfectly serviceable, not having shown any serious defects.

In conclusion, I may add that in attaining our present efficiency in naval engineering, we owe a great deal to the advice and help given by the British, many of our naval engineers having been educated in Great Britain.

1 yen = 2s. approximately.

BOW WORKS, STRATFORD: BOILER EXPLOSION.—We are informed that the formal investigation ordered by the Board of Trade to be held in this matter is fixed for hearing in the Town Hall, Broadway, Stratford, Essex, on Wednesday, August 2, at 11 a.m.

ADVERTISEMENT RATES.

The charge for advertisements is three shillings for the first four lines or under, and eightpence for each additional line. The line averages seven words. Payment must accompany all orders for single advertisements, otherwise their insertion cannot be guaranteed. Terms for displayed advertisements on the wrapper and on the inside pages may be obtained on application. The pages are 12 in. deep and 9 in. wide, divisible into four columns of 2¼ in. in width. Serial advertisements will be inserted with all practicable regularity, but absolute regularity cannot be guaranteed.

Advertisements intended for insertion in the current week's issue must be delivered not later than 5 p.m. on Thursday. In consequence of the necessity for going to press early with a portion of the edition, alterations for standing advertisements should be received not later than 1 p.m. on Tuesday in each week.

SUBSCRIPTIONS, HOME AND FOREIGN.

"ENGINEERING" can be supplied direct from the Publisher post free, for twelve months, at the following rates, payable in advance:—

For the United Kingdom	£1	9	2
For Canada—			
Thin paper copies	£1	11	6 ($7.65)
Thick ,,	£1	16	0 ($8.75)
For all other places abroad—			
Thin paper copies	£1	16	0
Thick ,,	£2	0	6

When foreign subscriptions are sent by Post-Office Orders, advice should be sent to the Publisher.

All accounts are payable to "ENGINEERING," LIMITED. Cheques should be crossed "Union of London and Smith's Bank, Limited, Charing Cross Branch." Post-Office Orders should be made payable at Bedford-street, Strand, W.C.

Offices for Publication and Advertisements, 35 and 36, Bedford-street, Strand, London, W.C.
